appearing side by side, often more numerous at one pole. Except for its unilateral location, lack of extrarenal cyst formation, and the fact that these patients show no genetic background or progressive deterioration in renal function, the gross and histologic findings are indistinguishable from those of asymmetrical ADPKD (Kossow and Meek, 1982; Lee et al., 1978). It is important not to overdiagnose unilateral simple cyst disease, because the entity itself is rare, and when first identified in an individual it is more likely to represent a unilateral asymmetrical presentation of ADPKD. Because the entity seems to represent nothing more than multiple simple cysts lying side by side within a kidney, it seems reasonable to consider it as a variation of the presentation of simple cysts. Now that genetic studies are becoming available for ADPKD, TSC, and VHL disease, the diagnosis of unilateral renal cystic disease can more readily be confirmed (Fig. 39.26).

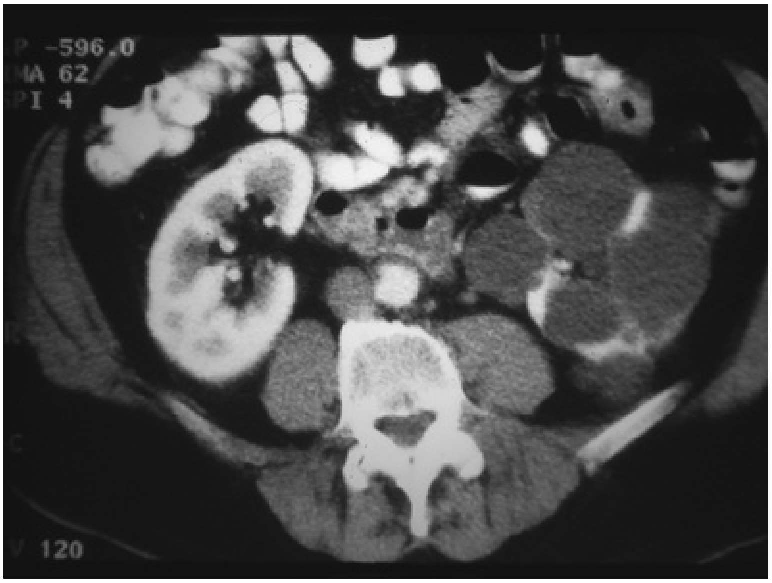

FIG. 39.26 Unilateral renal cystic disease. Diffuse simple cysts were evident in one kidney. There was no discrete mass or evidence of multiple malformation syndrome. (Courtesy Jeffrey Newhouse, MD.)

Key Points: Simple Cysts

- Simple cysts are seldom seen in children; in adults, simple cysts are seen increasingly more frequently with age.

- For diagnosis of a benign simple cyst on ultrasonography, it should (1) have no internal echoes, (2) have a sharply defined, thin, distinct smooth wall, (3) be spheric or oval with no internal echoes, and (4) have good transmission of sound waves with acoustic enhancement behind the cyst. When these criteria are not met, CT with contrast enhancement must be performed.
- Relevant guidelines for determining when to explore or remove a complex cyst are often based on the Bosniak CT classification (see Box 39.2).

Medullary Sponge Kidney

The condition known as *medullary sponge kidney* (MSK; also known as *precalyceal canalicular ectasia*) was recognized by Beitzke in 1908, and its radiographic features were described by Lenarduzzi in 1939. The name of this disorder dates from a 1949 publication by Cacchi and Ricci. **It is characterized by tubular dilation of the distal portion of the collecting ducts with numerous associated cysts and diverticula strictly confined to the medullary pyramids.** These dilated ducts have the appearance of the bristles on a brush and often are more ectatic and filled with calcifications, giving an appearance suggestive of a bouquet of flowers. In general, classic intravenous urography is more sensitive than CT in detecting mild cases of MSK; however, three-dimensional (3D) volume-rendered imaging acquired during the urographic phase of a multidetector CT urogram can also establish the diagnosis (Fig. 39.27). The current literature suggests that single-slice helical CT, ultrasonography, and MRI are not able to detect findings specific to MSK. However, CT urography with 3D volume-rendered imaging is comparable with intravenous pyelography for the diagnosis of MSK (Maw, 2007).

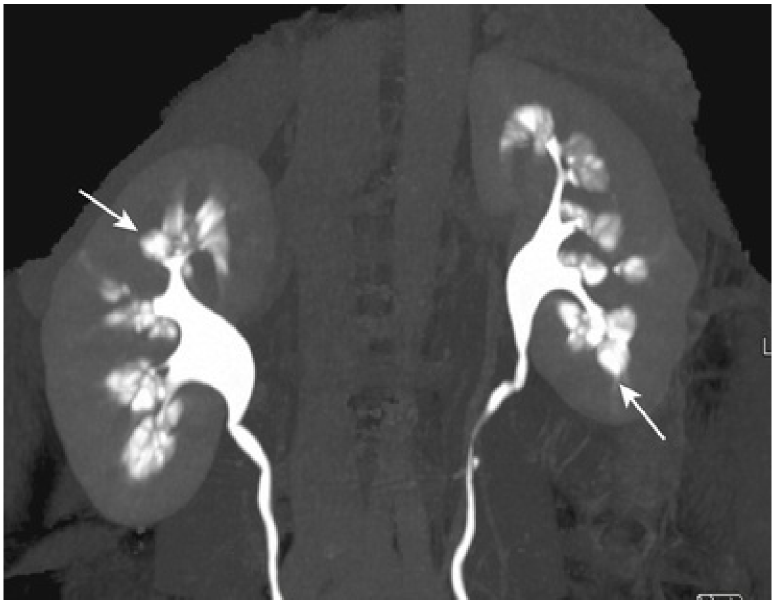

FIG. 39.27 Contrast-enhanced maximum intensity projection three-dimensional image from multidetector-row computed tomography (CT) urogram shows characteristic papillary blush *(arrows)* associated with scattered calculi within the dilated collecting tubules. The CT demonstration

is equivalent to the well-documented intravenous pyelography findings. (From Maw AM, Megibow AJ, Grasso M, et al.: Diagnosis of medullary sponge kidney by computed tomographic urography. *Am J Kid Dis* 50:146–150, 2007.)

A significant number of patients with MSK are asymptomatic, and their condition is never diagnosed. As a result, the true incidence of the condition is unknown. Among patients undergoing intravenous urography for various indications, 1 in 200 were found to have MSK (Myall, 1970; Palubinskas, 1961). MSK is more common in calcium stone formers. It is usually regarded as a nonhereditary disease, and the small number of reported cases in children implies that this is an acquired rather than a congenital disease. There has been some recent evidence, however, that some forms of the disease are inherited in an autosomal dominant fashion. This evidence supports the hypothesis that MSK is caused by a disruption at the ureteric bud–metanephric blastema or RET/GDNF interface (Gambaro, 2013).

Clinical Features

MSK is usually a benign process, and it may remain asymptomatic and undetected for life. Clinical presentation usually occurs after age 20 years, with the most common presentation being renal colic (50% to 60%), followed by urinary tract infection (20% to 33%) and gross hematuria (10% to 18%) (Kuiper, 1976). The incidence of MSK in stone formers differs widely in the reported series, ranging from 2.6% to 21%. The incidence appears to be higher in female than in male stone formers (Lavan et al., 1971; Palubinskas, 1961; Parks et al., 1982; Sage et al., 1982; Vagelli et al., 1988; Wikstrom et al., 1983; Yendt, 1990). Urinary tract infections, likewise, seem to be more common in female patients with MSK (Parks et al., 1982).

One-third to one-half of the patients with MSK have hypercalciuria (Ekstrom et al., 1959; Harrison and Rose, 1979; Parks et al., 1982; Yendt, 1990). Incomplete distal renal tubular acidosis may be found in as many as 30% to 40% of these patients (Torres and Grantham, 2008). In the absence of infection, the stones passed by patients with MSK are composed of calcium oxalate, either alone or in combination with calcium phosphate. MSK has also been reported in association with rare congenital anomalies, such as hemihypertrophy, Beckwith-Wiedemann syndrome (macroglossia, omphalocele, and gigantism), Ehlers-Danlos syndrome, anodontia, and Caroli disease.

Three different clinical pictures of MSK have been described: the typical form characterized by recurrent calcium nephrolithiasis and a number of concomitant tubular defects, including renal acidosis and metabolic bone disease; an indolent form with no or few renal stones and no tubular defects; and a rare but very severe condition dominated by intractable excruciating renal pain (Gambaro, 2013).

Histopathology

The principal finding is dilated intrapapillary collecting ducts and small medullary cysts, which range in diameter from 1 to 8 mm and give the cross-sectioned kidney the appearance of a sponge. The renal size is usually normal or slightly enlarged. The precalyceal canalicular ectasia may involve one or more renal papillae in one or both kidneys. The lesions are bilateral in 70% of cases. The cysts are lined by collecting duct epithelium (Bernstein, 1990) and usually communicate with the collecting tubules. The cysts and the dilated collecting ducts may have concretions mostly made of pure apatite (calcium phosphate) and, less frequently, apatite and calcium oxalate (Ekstrom et al., 1959). The cysts contain a yellow-brown fluid and desquamated cells or calcified material.

Diagnosis

The urographic features of the disorder are as follows: (1) enlarged kidneys, sometimes with calcification, particularly in the papillae; (2) elongated papillary tubules or cavities that fill with contrast medium; and (3) papillary contrast blush and persistent medullary opacification (Gedroyc and Saxton, 1988). Calcium deposits within the tubules may appear as renal calculi or nephrocalcinosis.

In rare cases, MSK can mimic the radiographic appearance of ADPKD. In these instances, the liver should be evaluated before a diagnosis is made. In addition, the absence of family history and a CT showing the absence of cortical cysts help confirm the diagnosis.

When nephrocalcinosis is found, other hypercalciuric states, such as hyperparathyroidism, sarcoidosis, vitamin D intoxication, multiple myeloma, tuberculosis, and milk alkali syndrome, must be ruled out. In these conditions, the calcium deposits are in collecting ducts of normal caliber, whereas in MSK the calcifications occur in dilated ducts (Levine and Grantham, 1990).

Treatment and Prognosis

The complications of MSK, calculus formation and infection, require management. Given the frequent presence of hypercalciuria and hypocitraturia (possibly caused by incomplete renal tubular acidosis), treatment with potassium citrate is effective in reducing the rates of calciuria and stone recurrence (Gambaro, 2013). In addition to liberal fluid intake and a low-sodium diet, **thiazides are effective for lowering hypercalciuria and limiting stone formation. If thiazides cannot be used, inorganic phosphates may be appropriate;** however, they should not be used in patients with urinary tract infections caused by urease-producing organisms, because of the risk of struvite stones. **For patients with renal lithiasis, thiazides should be administered even if hypercalciuria is not present.**

Because infections are not unusual in patients with MSK, especially if stones are present, cultures should be obtained frequently, and long-term prophylaxis should be considered in some cases. Infections by coagulase-positive staphylococci are common in patients with stones and should be treated even when the colony count in the cultures is less than 100,000/mL (Yendt, 1990). Repeated investigations for hematuria should be avoided. When stones require surgical therapy, standard procedures, such as extracorporeal lithotripsy and percutaneous nephrolithotomy, may be used.

Key Points: Medullary Sponge Kidney

- MSK is usually a nonheritable condition associated with dilated collecting ducts that appear as bristles on a brush on IVP, and the ducts are sometimes filled with calcifications.
- There are high incidences of renal colic (50% to 60%), urinary tract infections (20% to 33%), gross hematuria (10% to 18%), and hypercalciuria (33%).

Sporadic Glomerulocystic Kidney Disease

GCKD is a specific entity, but the term has often been used to include all conditions in which there are glomerular cysts, regardless of cause. The term *glomerulocystic* means that cysts of the glomeruli or Bowman space are present diffusely and bilaterally. However, cysts of the glomeruli are present in many forms of renal cystic disease, and they may or may not be the predominant pathology. The specific disease entity, glomerulocystic disease (or “sporadic” glomerulocystic disease), is a nonheritable condition producing bilaterally enlarged kidneys containing small cysts, predominantly of the Bowman space. The clinical significance of this disease process is that it is often **indistinguishable from other conditions in which glomerular cysts are present, namely, autosomal dominant polycystic disease, familial hypoplastic glomerulocystic disease, and juvenile NPH.** Characteristically, with sporadic GCKD, no other family members are affected and no associated anomalies are typically present.

Acquired Renal Cystic Disease

ARCD, also known as *acquired cystic kidney disease* (ACKD), is defined as bilateral cystic renal change in patients with ESRD from causes other than inherited renal cystic disease. A minimum of three cysts in each kidney is required for diagnosis. This disease entity was first described in 1977 in **patients receiving hemodialysis; however, it soon became apparent that the disorder is almost as common in patients receiving peritoneal dialysis** (Dunhill et al., 1977; Thomson et al., 1986). It is now known that dialysis is not a prerequisite of ARCD, and it is likely that the uremic state causes the pathologic changes seen; dialysis merely prolongs patient survival and the amount of time available for the cystic changes to occur (Fisher and Horvath, 1972; Ishikawa et al., 1980; Kutcher et al., 1983; Miller et al., 1989; Truong et al., 2003).

The prevalence and severity of this disease increase with the duration of azotemia and the subsequent need for dialysis. Acquired cysts are found in roughly 10% of patients with ESRD before dialysis. The incidence increases to 44% within 3 years after initiation of dialysis, to 60% at 5 years after initiation of dialysis, and to greater than 90% if the patient is on dialysis for 10 or more years. ARCD is three times more common in men than in women and is generally thought to be unrelated to age or the cause of renal failure. African-Americans and perhaps Japanese are more prone than Americans of European descent to develop ARCD (Reichard et al., 1998). **ARCD can occur in children as well (an incidence of approximately 23% has been reported)** (Hakim et al., 1994). A successful renal transplant was previously thought to delay or even reverse the cystic changes, but this is not supported by more recent data (Doublet et al., 1997; Heinz-Peer et al., 1995; Kliem et al., 1997).

Etiology

Several etiologic theories have been proposed for ARCD, although the exact cause has not been identified. One theory suggests that tubular obstruction resulting from fibrosis, oxalate crystals, vascular occlusion, or ischemia leads to cyst formation. Various other findings suggest a role for toxins. First, the cysts, adenomas, and carcinomas usually are multiple and bilateral, as are the carcinomas induced experimentally in rats by toxins. Second, there is often a regression of the cysts after successful transplantation (Ishikawa et al., 1983), suggesting that some cystogenic or carcinogenic toxin of uremia is being eliminated by the allograft. Third, if transplantation fails and dialysis is resumed, the cysts return even in chronically rejected transplanted kidneys. Another hypothesis suggests that the accumulation of growth factors, such as epidermal growth factor (EGF), and other stimulatory chemicals (present with uremia) leads to the development of cysts (Bisceglia et al., 2006). Yet another theory suggests that loss of functioning renal tissue leads to the production of renotrophic agents that induce hyperplasia of remaining glomeruli, cyst development, and in extreme cases renal tumors (Harris et al., 1983; Yamamoto et al., 1983).

Clinical Features

Most patients with ARCD are asymptomatic. The majority of clinical manifestations result from spontaneous bleeding into one or more of the cysts, making the most common presentation loin pain, hematuria, or both conditions. Bleeding occurs in as many as 50% of patients (Levine, 1996). When significant bleeding occurs, it may cause a subcapsular or retroperitoneal hematoma and may be secondary to renal cysts or to RCC. This bleeding may be complicated by coagulation defects induced by uremia or heparinization during dialysis. Other, much less common, complications are cyst infection, urolithiasis, and a rapid rise in hematocrit, which is probably related to increased renal synthesis of erythropoietin (Mickisch et al., 1984; Ratcliffe et al., 1983; Shalhoub et al., 1982). Patients with microscopic hematuria (more than 5 red blood cells per high-power field), dialysis patients, and transplant recipients should be radiographically evaluated because of the increased risk of tumor formation in these groups.

Renal neoplasms, principally adenomas, occur in 10% of patients receiving chronic hemodialysis, and, when ARCD is present, the incidence of neoplasms is even higher, ranging from 20% to 25% (Gardner and Evan, 1984). The overall prevalence of RCC in hemodialysis patients is approximately 1%. Carcinoma is 3 times more likely in the presence of ARCD and 6 times more common in large cystic kidneys than in small cystic kidneys (Torres and Grantham, 2008). **Overall, the incidence of renal malignancy in dialysis patients is 5 to 50 times greater than in the general population** (Ishikawa, 1993; Levine et al., 1991; Port et al., 1989; Resseguie et al., 1978; Truong et al., 1995).

Compared with the sporadic form, RCC associated with ARCD is characterized by younger patient age, male predominance, frequent multicentricity and bilaterality, and less aggressive behavior (Denton et al., 2002; Gronwald et al., 1999; Truong et al., 2003). Approximately 20% of ARCD-associated RCC metastasizes versus 50% for sporadic RCC. **The risk factors for tumor development include male gender, duration of dialysis, and kidney weight, but not type of dialysis.** Children on dialysis can also develop RCC, despite its rarity in the general pediatric population. Most tumors (86%) are asymptomatic, and the symptomatic ones are related mostly to bleeding from tumor. Many manifest exclusively as persistent hematuria and are not seen by any available imaging techniques. Nephrectomy is recommended for tumors larger than 3 cm or for smaller ones that are associated with persistent hematuria or rapid growth (Ishikawa, 2000; Truong et al., 1995).

Histopathology

Both kidneys are usually smaller than normal, and the cysts are multiple and bilateral. The cysts develop predominantly in the cortex, although the medulla may be affected, especially later in the disease process (Fig. 39.28). The cysts average 0.5 to 1.0 cm in diameter, but some have been reported to reach 5.0 cm (Miller et al., 1989). Larger cysts, a frequent feature of ADPKD, are rare. The cysts are unilocular and contain clear, straw-colored, or gelatinous fluid, with frequent bleeding and/or neoplastic transformation.

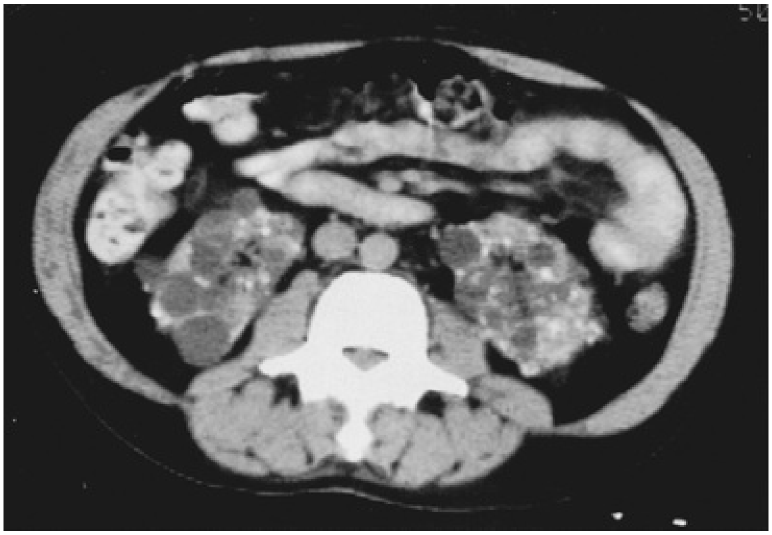

FIG. 39.28 Bilateral multiple renal cysts and diffuse calcification in enlarged kidneys in a patient undergoing chronic hemodialysis. The

findings simulate those of ADPKD. However, cystic disease was not the cause of the uremia, and the diagnosis of acquired renal cystic disease was made. (Courtesy D. Gordon, MD.)

Most cysts are lined by a single layer of epithelium composed of flat nondescript cells, cells with abundant cytoplasm and hyaline droplets, or small cuboidal cells resembling those from distal tubules or collecting ducts. Cysts usually show secondary changes, including luminal deposition of degenerated blood, hemosiderin, or calcium oxalates (Hughson et al., 1986; Ishikawa, 1991; Truong et al., 1995). The nuclei of the epithelial cells in these cases are round and regular, without prominent nucleoli (Hughson et al., 1980). However, some cysts (atypical or hyperplastic) are lined by epithelial cells with larger, irregular nuclei that contain prominent nucleoli and may show mitotic activity. This hyperplastic lining is thought by some to be a precursor of renal tumors. Moreover, some hyperplastic cysts have papillary projections, and to some observers the distinction between cyst and neoplasm becomes blurred when papillary hyperplasia predominates.

Differentiating renal tumors into adenomas and carcinomas is arbitrary at times. Most renal nodules that are smaller than 1 cm in diameter are adenomas, and most that are larger than 3 cm in diameter are carcinomas. Tumors between 1 and 3 cm in diameter must be considered equivocal. It is not clear whether renal adenomas undergo malignant transformation. It is believed that atypical hyperplastic epithelium occurs even without cyst formation and that these cells are the precursors of atypical cysts and adenomas (Hughson et al., 1986). It is thus possible that either hyperplastic cysts or adenomas can become RCCs. Therefore the clinician must not ignore the native kidney left in situ during a renal transplantation. Hyperplastic cyst epithelium has also been considered a possible precursor of RCC in other cystic diseases (VHL disease and tuberous sclerosis) (Fayemi and Ali, 1980).

Evaluation

Ultrasonography is the modality most commonly used to diagnose and monitor patients with ARCD. CT and MRI identify more cysts, and MRI is probably better at demonstrating and characterizing small lesions in particular (Heinz-Peer et al., 1998). Ultrasonography usually shows small, hyperechoic kidneys with cysts of various sizes. Cyst wall calcification may be visible, but it is more readily seen on CT. CT with and without contrast is better for distinguishing kidneys with a few simple cysts from those with multiple acquired cysts and is the most useful for detecting neoplasms. In patients with ESRD not yet on dialysis, however, the use of CT contrast should be avoided for fear of causing further deterioration of renal function. Ultrasonography and MRI with gadolinium enhancement are better alternatives to contrast-enhanced CT in these patients. **A word of caution, however: nephrogenic systemic fibrosis (NSF) is a rare but serious and life-threatening disorder observed in patients with renal impairment and is associated with the infusion of gadolinium as an MRI contrast agent in patients with ESRD. Caution should be used when using gadolinium in these patients.**

In uremic patients with fever, clinicians should consider the diagnosis of ARCD and the possibility of an infected cyst (Bonal et al., 1987). Infection should be suspected if ultrasonographic examination shows internal echoes or a thickened wall. Cyst puncture can be used to confirm the diagnosis and to identify the infecting microorganism. CT examination may identify cyst wall thickening in patients with infection.

In the differential diagnosis of ARCD, the cause of the renal failure must be considered and, in particular, the possibility of ADPKD. Usually, patients with ARCD have smaller kidneys and smaller cysts and are free of the extrarenal manifestations of ADPKD. In patients receiving hemodialysis, kidneys affected by ARCD usually are smaller than 300 g; ADPKD kidneys usually are larger than 800 g (Feiner et al., 1981).

Treatment

Bleeding episodes are often treated conservatively with bed rest and symptom control. Persistent bleeding and pain, however, may require nephrectomy or renal embolization. If heparinization is associated with hematuria during hemodialysis, peritoneal dialysis may be substituted. Because the risk of undetected RCC is high in patients with retroperitoneal hemorrhage, nephrectomy is recommended when carcinoma cannot be ruled out. If a few larger cysts are associated with flank pain, percutaneous aspiration (with cytologic examination) is a reasonable temporizing measure, because ARCD may regress after successful renal transplantation (Torres and Grantham, 2008). For an infected cyst, percutaneous drainage may be effective. When it is not, surgical drainage or nephrectomy should be considered.

Although small renal tumors may metastasize, it is known that those smaller than 3.0 cm in diameter rarely do so (Bell, 1935; Talamo and Shonnard, 1980). Thus it is currently recommended that renal masses larger than 3 cm detected in patients with ACKD be treated by surgical excision. For tumors smaller than 3 cm, some advise nephrectomy for the acceptable surgical candidate, whereas others recommend annual CT follow-up with resection only if the tumors enlarge. Although metastases are statistically less likely to occur from small than from large tumors, small tumor size is not a guarantee against metastasis. Laparoscopic bilateral radical nephrectomy in patients with ESRD, ACKD, and suspicious tumors has been proposed as a more desirable alternative to traditional open surgery (Ghasemian et al., 2005).

It has been recommended that patients who have been receiving hemodialysis for longer than 3 years be screened by ultrasonography and CT and then monitored by ultrasonography every 6 months if the kidneys are without cysts and tumors or by both ultrasonography and CT on the same schedule if cysts or tumors smaller than 2 cm are identified (Sarasin et al., 1995). The benefit of screening in this population continues to be the subject of much debate. It has been proposed that screening be restricted to patients younger than 55 years who have been on dialysis for at least 3 years and are in good general health (Sarasin et al., 1995). Others have suggested that screening of patients should be considered when known risk factors exist, such as prolonged dialysis, presence of ARCD, and male gender (Reichard et al., 1998).

A number of investigators have found that the cysts of ARCD regress after renal transplantation (Ishikawa et al., 1983; Kutcher et al., 1983; Thomson et al., 1986). Therefore it was considered that the incidence of RCC may fall after transplantation as well. Unfortunately, 18% of patients developed new cysts after transplantation, and renal carcinoma can occur in the native kidney 3 to 8 years after transplantation (Ishikawa, 1991; Levine and Gburek, 1994). It appears that the malignant potential of ARCD may persist for many years after transplantation, especially in older transplantation patients and in men (Heinz-Peer et al., 1995). Finally, immunosuppression makes these patients vulnerable to carcinoma. Native kidneys account for 4.5% of all malignancies in renal transplantation recipients (Penn, 1979). After renal transplantation for ESRD, the risk for developing RCC is more than 15-fold increased (Kasiske, 2004). RCC of native kidneys and RCC of the allografts can be distinguished, with more than 70% of the tumors occurring in native kidneys (Klatte, 2011; Tsaur, 2011). It also appears that the clinical significance of RCC in patients undergoing chronic hemodialysis must be questioned because in this population, RCCs rarely cause metastases or death. In contrast, renal cancer in the transplant population behaves aggressively and warrants aggressive evaluation before and after renal transplantation.

Key Points: Acquired Renal Cystic Disease

- ARCD is associated with chronic renal failure and is most often seen in patients on long-term hemodialysis and peritoneal dialysis.
- ARCD consists of hyperplastic renal cysts and frequently adenomas; either can progress to RCC.
- The incidence of renal malignancy in dialysis patients is 5 to 50 times greater than in the general population. If RCC develops, it mostly does so before 10 years of dialysis.
- The cysts usually regress with transplantation. Even when this occurs, there still is some suggestion that the risk of developing RCC still persists, but at a much lower incidence.

Calyceal Diverticulum (Pyelogenic Cyst)

A calyceal diverticulum is an outpouching of the collecting system into the corticomedullary region of the kidney, and it usually arises from the fornix of a calyx. It is a transitional epithelial-lined, smooth-walled, spheric cavity that communicates with the pelvicalyceal system by a thin channel or neck, typically in the upper or lower pole. It is sometimes known as a *pyelogenic cyst*, especially if it arises from the renal pelvis. The size of such lesions can range from a few millimeters to several centimeters. Most diverticula are presumed to be congenital; however, similar lesions may occur as a result of blunt renal trauma or obstruction of a calyceal infundibulum. Diverticula are usually asymptomatic but may occasionally develop calculi. The calculi may be a single larger stone or multiple tiny stones. Occasionally, milk of calcium may be present. Passage of a stone through the narrow channel into the calyx may cause pain and hematuria.

Radiographically, these diverticula are seen as a spheric collection of contrast medium adjacent to a papilla on IVP; however, the connecting channel is often too narrow to be demonstrated. On upright films, the urine and contrast media form a fluid level. Calyceal diverticula can also be seen on CT, MRI, and ultrasonography, but the distinction between an obstructed calyx and a renal cyst may be difficult unless contrast is administered (Fig. 39.29).

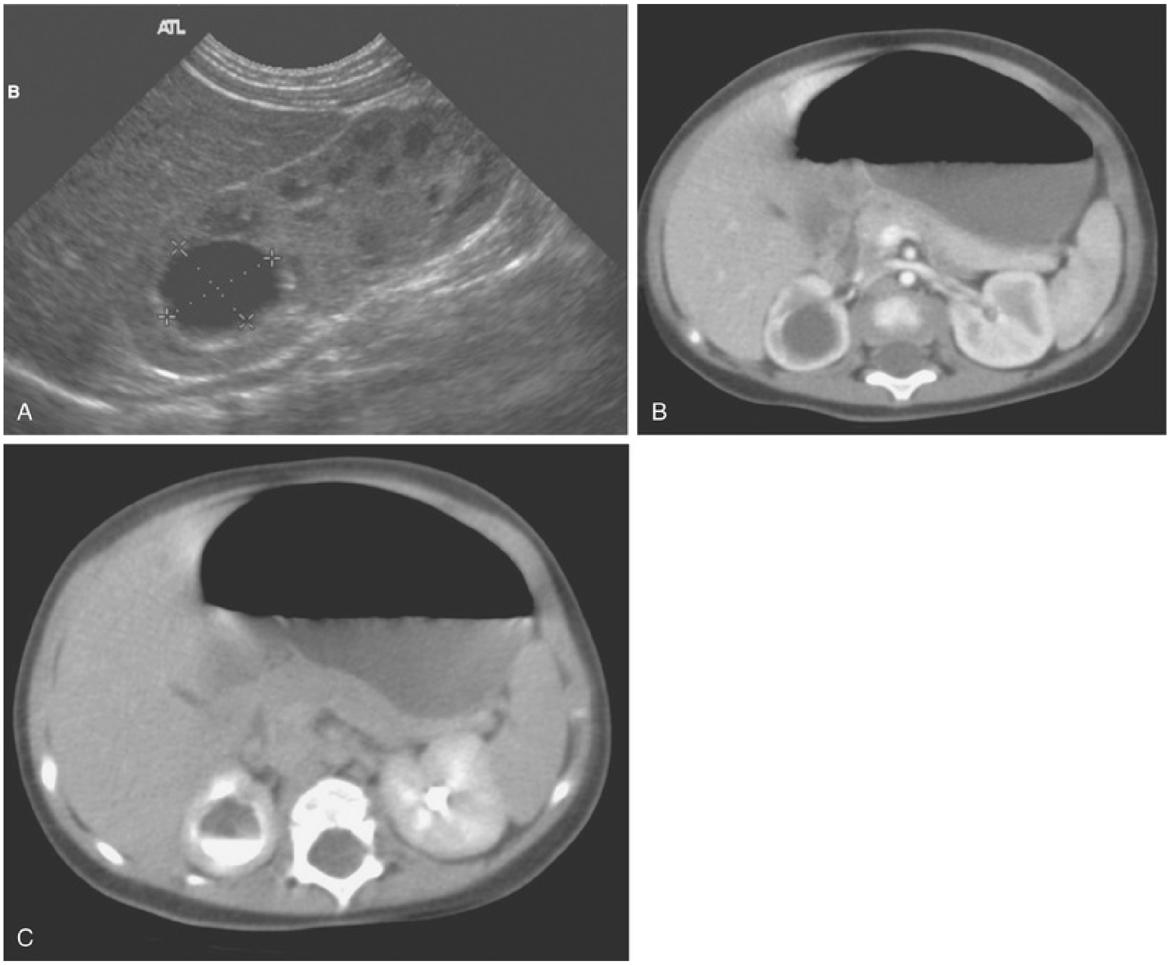

FIG. 39.29 Calyceal diverticulum. (A) Renal ultrasonography reveals a round lesion that could be confused with a renal cyst. Because of the patient's history of recurrent febrile urinary tract infections, contrast computed tomography was performed. (B) Early contrast images reveal no enhancement of the lesion; however, delayed imaging (C) reveals contrast layering in a portion of the collecting system, confirming the diagnosis of calyceal diverticulum.

This entity is discussed in more depth in Chapter 38.

Parapelvic and Renal Sinus Cysts

Parapelvic cysts, renal sinus cyst, peripelvic cyst, pelvic cyst, parapelvic lymphatic cysts, hilus cysts, cysts of the renal hilum, and parapelvic lymphangiectasia are terms used to describe cysts adjacent to the renal pelvis or within the hilum. Although some peripelvic cysts are simple cysts that arise from the renal parenchyma and impinge on the renal pelvis, true cysts derived from the renal sinus have no parenchymal cause. Thus the terms *parapelvic* and *peripelvic* are terms better used to describe the location of parenchymal cysts, and the term *renal sinus cyst* more accurately describes all other cysts in the hilum that are not derived from the renal parenchyma but rather from the other structures of the renal sinus, such as arteries, lymphatics, and fat. These are all benign lesions found in 15% to 20% of patients at autopsy. With modern imaging techniques, they can easily be distinguished from more serious lesions of the renal pelvis or renal parenchyma (Fig. 39.30).

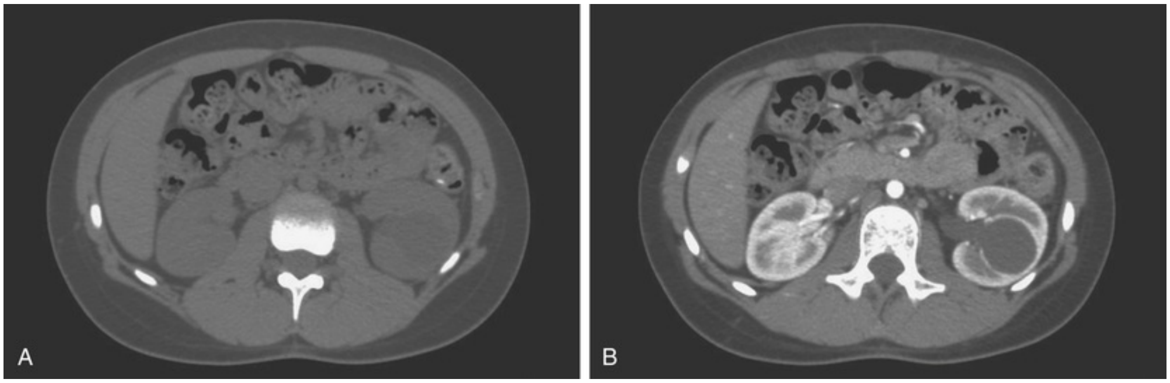

FIG. 39.30 Parapelvic cyst. (A) A hypoechoic, well-circumscribed, round focus in the peripelvic region of the kidney. (B) There is no delayed enhancement after the administration of intravenous contrast. There is no hydronephrosis or hydroureter. Note contrast within the ureter on the contrasted images.

The predominant type of renal sinus cyst appears to be a result of dilation of lymphatics; however, the mechanism responsible for these changes is not known. Most often these cysts are multiple, and often they are bilateral. Other renal sinus cysts are caused by fluid replacing adipose tissue in the renal sinus as the kidney becomes affected by local vascular disease and atrophy.

Patients are usually in their fifth or sixth decades and are almost always asymptomatic. These cysts are usually discovered incidentally in the course of evaluation for other conditions, such as urinary tract infections, nephrolithiasis, hypertension, and prostatism. There are rare instances of obstruction of a collecting system from these cysts. Ultrasonography will show multiple echo-free areas in the region of the renal sinus. Differentiation from hydronephrosis may be difficult. A diagnosis of hydronephrosis is established without question when dilated calyces are seen to communicate with a dilated renal pelvis. On CT, renal sinus cysts have the attenuation value of water, and they can often be seen within the renal sinus as they displace the calyces peripherally. On nonenhanced scans, multiple renal sinus cysts resemble a dilated renal pelvis and thus mimic hydronephrosis. Differential diagnosis should include renal sinus lipomatosis (fat density), lymphoma, hemorrhage, and urinoma. The therapeutic approach to renal sinus cysts should be conservative.

Pathophysiology of Urinary Tract Obstruction

Craig A. Peters MD, Kirstan K. Meldrum MD

Prevalence

Obstructive uropathy accounts for approximately 10% of all cases of renal failure. In an autopsy series of 59,064 individuals ranging from neonates to geriatric subjects, the prevalence of hydronephrosis was originally estimated to be 3.1% (Bell, 1950). Hydronephrosis was found to be more prevalent in women between ages 20 and 60, which was attributed to pregnancy and the development of gynecologic malignancies. In contrast, hydronephrosis was more prevalent in males after age 60 because of the presence of prostatic disease.

In a consecutive autopsy series of 3172 stillbirths, infants, and children performed over a 12-year period, urinary tract malformations were found in 78 cases (2.5%). Hydronephrosis and/or hydroureter accounted for 35.9% of urinary tract abnormalities (Tan et al., 1994). A slightly higher autopsy incidence of hydronephrosis in children (2%) was reported by Campbell (1970). Among children, hydronephrosis appears to be somewhat more prevalent in boys, and the majority of cases occur in subjects younger than 1 year. Indeed, obstructive nephrouropathies constitute the single largest entity leading to renal insufficiency in male children younger than 1 year of age (Benfield, 2003; Seikaly et al., 2003; USRDS, 2015).

Clinical Presentation of Obstruction

The clinical presentation of urinary tract obstruction can be variable depending on the site, degree, and chronicity of the obstruction. Flank pain secondary to stretching of the collecting system is the most common symptom in patients with acute obstruction and is typically an unrelenting, excruciating pain that can radiate to the lower abdomen and testicles or labia on the affected side and is often associated with nausea or vomiting. In contrast, chronic obstruction of the urinary tract is usually a relatively painless phenomenon, and patients may be entirely asymptomatic. Obstruction of the bladder outlet is most often associated with voiding symptoms of frequency, urgency, hesitancy, nocturia, poor urinary stream, and the sensation of incomplete emptying. Anuria is a rare but dramatic and fairly specific presenting sign of urinary tract obstruction.

Obstructive uropathy should always be considered in patients with new-onset hypertension and in patients with renal failure without a previous history of renal disease, diabetes, or hypertension. In addition, urinary tract obstruction should always be investigated as a possible contributing factor in patients with recurrent urinary tract infections (UTIs). Because the clinical signs and symptoms of obstructive uropathy are so variable, the diagnosis is dependent on prompt and appropriate imaging.

Clinical Presentation in Children

Prenatal ultrasonographic diagnosis has radically altered the clinical presentation of obstructive conditions. Today most are detected before birth, and many have no apparent clinical signs. Those with clinical manifestations are often severe obstructive conditions such as posterior urethral valves or massive hydronephrosis of various causes. Children are still found with clinical signs of obstruction, usually infection or pain, and rarely hypertension (de Waard et al., 2008). In the child with obstruction of the entire urinary tract, even when the obstruction is relieved, the functional abnormalities inform us of the effects of obstruction on developing kidneys. Reduced filtration function resulting from glomerular injury can cause a rising serum creatinine, acidosis due to tubular injury, and nephrogenic diabetes insipidus secondary to collecting duct abnormalities. In extreme cases, these may all be present, but on occasion they are noted in isolation and may persist after relief of the obstruction

(Hutcheon et al., 1976). Obstructive hypertension appears to be renin mediated (Mizuiri et al., 1992; Riehle and Vaughan, 1981; Urata et al., 1985) and may be reversible with surgical repair (Al-Mashhadi et al., 2015; de Waard et al., 2008).

Progressive Renal Dysfunction

A major concern regarding obstructive conditions in the urinary tract is the potential for progressive renal dysfunction. Progression may be seen in two forms, one with the uncorrected partially obstructive lesion (i.e., ureteropelvic junction [UPJ] obstruction), and the second with the previously obstructed but corrected obstruction that has produced some degree of renal damage (i.e., posterior urethral valves). In the first, renal function may initially appear intact on imaging tests, yet in time there will be loss of absolute and relative function of the kidney affected by the obstruction. If this were known prospectively, intervention would be appropriate and should be performed early. The challenge is in predicting this situation and few markers are available to do this. The frequency of progressive deterioration in unilateral asymptomatic obstruction likely ranges from 20% to 40%, but severity and duration of follow-up will significantly affect this rate. Every prospective study of obstructive conditions has documented the potential for progressive loss (Koff, 2000; Koff and Campbell, 1992, Palmer et al., 1998; Parkhouse et al., 1988; Ross et al., 2011; Thorup et al., 2003).

The second situation reflects the fact that the damaged kidney does not have the functional reserve of a normal kidney. These kidneys demonstrate a steady decline in function over time, and this is usually evident only in bilateral obstruction. The mechanism may be hyperfiltration of remnant renal units, and clinically this is most often seen with posterior urethral valves (Heikkila et al., 2011; Nguyen and Peters, 1999; Parkhouse et al., 1988). These children may show adequate renal function early in life yet demonstrate a delayed and inexorable progression into renal failure in adolescence (Fig. 40.1). Whether earlier intervention would have protected their renal function is uncertain. Ultimately, specific therapeutic interventions could be targeted toward prevention of this progressive process (Chevalier, 2015).

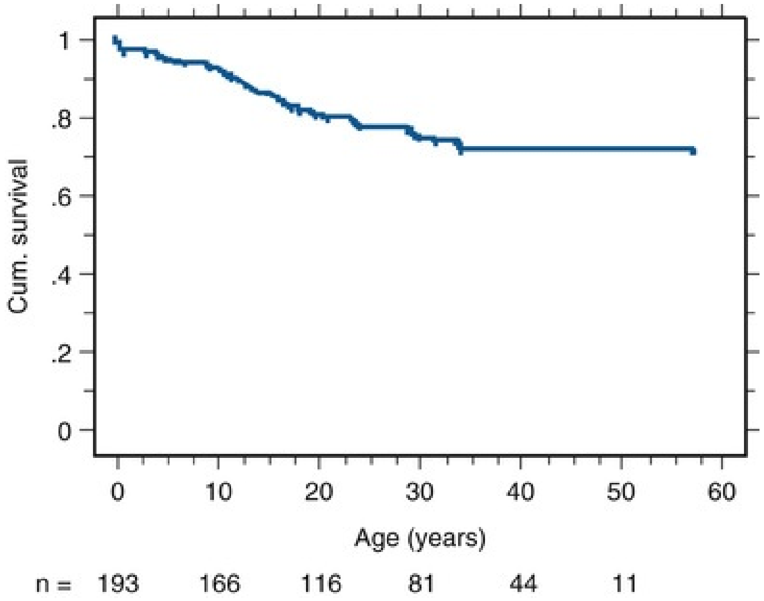

FIG. 40.1 Graph depicting the progressive deterioration in renal function and progression to end-stage renal disease in children with posterior urethral valves. (From Heikkilä J, Holmberg C, Kyllönen L, et al.: Long-term risk of end stage renal disease in patient with posterior urethral valves. *J Urol* 186:2392–2396, 2011. With permission.)

The most obvious marker of progressive renal dysfunction is the serum creatinine. However, this is relatively insensitive in early stages of progression. Radionuclide imaging may be helpful in some cases, but there is no gold standard regarding the best interpretation of potentially progressive disease. Urinary biomarkers have been extensively investigated, yet none are used commonly (Chevalier, 2016; Madsen et al., 2011).

Definition of Obstruction

Although the detection of hydronephrosis is straightforward, the determination of whether this particular condition requires surgical intervention to protect renal function and development is much more difficult. The frequently quoted definition of congenital obstruction (Koff, 1987) is that of “a condition producing a restriction of urinary flow that will lead to deterioration in renal function” seems too limited. In the growing child, renal function is expected to increase significantly, initially in excess of body mass and subsequently in parallel to it. If this increase in function does not occur, renal functional potential is lost, which may be of greater consequence than losing absolute function. Therefore **the impairment of renal functional development should be considered as a determinant of obstruction that warrants intervention** (Peters, 1995).

If this is the case, then an obstructive or hydronephrotic condition associated with less than normal function should be considered as likely functionally obstructive and warranting intervention. The ability to recover function that has not been achieved is unpredictable, however.

A critical element of COU is the recognition that it is distinct from acquired obstruction in the mature animal (or mature kidney). The fact that obstruction develops at the same time the kidney is in the process of formation creates an entirely different paradigm for COU as compared with obstruction of the mature kidney (Peters, 1997). The patterns of renal development are affected by obstruction, and this produces the ultimate functional effects. The mechanisms for these alterations are therefore wholly distinct from mature obstruction. Although there is likely to be some overlap in the critical mechanisms of change, many will be different.

One of the frustrations in the management of clinical congenital obstruction is the dichotomy between therapeutic options, which are currently limited to either observation or surgery. The absence of any medical or pharmacologic therapy to ameliorate or prevent the complications of obstruction has been a major factor in the controversy between those who chose to correct a problem and those who believe it is better to await spontaneous resolution or unambiguous evidence of obstructive injury. The horizon holds promise for medical therapies that may prevent renal injury in various ways, but it will be essential to more completely understand the nature of COU to permit such specific treatment. As medical therapies evolve, the simplistic black and white view of obstructed vs. not obstructed, rooted in our limited treatments, will hopefully fade away as it should.

Diagnosis and Imaging

Laboratory Studies

The initial workup of a patient suspected of having urinary tract obstruction should begin with a urinalysis and microscopic analysis. An assessment of renal function and measurement of serum electrolytes should be performed, and in the patient with acute renal failure, an assessment of urinary diagnostic indices including the fractional excretion of sodium (FENa) should be performed.

Urinalysis

The urinalysis and microscopic analysis is necessary in the complete evaluation of a patient suspected of having urinary tract obstruction and/or renal failure. The urinalysis can provide an estimation of osmolality, evidence of urinary tract infection, insight into stone formation based on crystals that may be present in the urine, and the possible presence of medical renal disease with the presence of protein and/or cellular casts.

Fractional Excretion of Sodium

The FENa is a test often used to differentiate between the three types of acute renal injury: prerenal, intrinsic, and postrenal.

$$\mathrm{FENa} = (P_{Cr} \times U_{Na})/(P_{Na} \times U_{Cr})$$

P_{Cr} is defined as the serum creatinine level, U_{Na} is urine sodium level, P_{Na} is serum sodium level, and U_{Cr} is the urine creatinine level. An FENa less than 1% suggests a prerenal cause of acute renal failure (i.e., hypovolemia, congestive heart failure [CHF], renal artery stenosis, sepsis). An FENa of more than 1% indicates intrinsic causes of acute renal failure (i.e., acute tubular necrosis, glomerulonephritis, acute interstitial nephritis), and an FENa more than 4% indicates postrenal causes of acute renal failure (i.e., BPH, bladder stones, bilateral ureteral obstruction).

Assessment of Renal Function

Measurement of glomerular filtration rate (GFR) is considered the gold standard in identifying patients with renal insufficiency or renal failure. Normal GFR varies and generally decreases with age. The measurement of true GFR can be tedious and impractical; therefore a variety of tests are used to estimate GFR, the most common being serum creatinine. Creatinine remains imprecise, however, because of variability with age, gender, race, and a relationship with muscle mass. In adults, the most accurate estimating equation for GFR is the Chronic Kidney Disease Epidemiology Collaboration equation (CKD-EPI) (Levey et al., 2009):

$$\begin{aligned} \text{eGFR} &= 141 \times \min\left(S_{cr}/\kappa, 1\right)^{\alpha} \times \max\left(S_{cr}/\kappa, 1\right)^{-1.209} \\ &\quad \times 0.993^{\text{Age}} \times 1.018\ [\text{if female}] \times 1.159\ [\text{if black}] \end{aligned}$$

where S_{cr} is serum creatinine in mg/dL, κ is 0.7 for females and 0.9 for males, α is −0.329 for females and −0.411 for males, *min* indicates the minimum of S_{cr}/κ or 1, and *max* indicates the maximum of S_{cr}/κ or 1. The Schwartz equation is most commonly used to estimate GFR in children:

$$\text{eGFR} = 0.413 \times \text{height (cm)}/\text{serum creatinine (mg/dL)}$$

Because creatinine is a waste product of muscle metabolism and is cleared by glomerular filtration and tubular secretion, serum creatinine can be influenced by a number of factors without representing a change in GFR. Cystatin C has recently emerged as a more accurate marker of GFR and can be used in modified CKD-EPI and Schwartz equations to estimate GFR (Pasala and Carmody, 2017). Cystatin C is a cysteine protease inhibitor produced by all nucleated cells in the body and is therefore not influenced by muscle mass. It is also freely filtered at the glomerulus and not secreted by the tubules (Pasala and Carmody, 2017).

In general, a GFR greater than 90 mL/min/1.73 m^2 is considered normal, between 60 and 90 mL/min/1.73 m^2 is considered a mild decline in renal function, between 30 and 60 mL/min/1.73 m^2 is a moderate decline in renal function, between 15 and 30 mL/min/1.73 m^2 is a severe decline in renal function, and less than 15 mL/min/1.73 m^2 is considered renal failure (Siddiqui and McDougal, 2011).

Biomarkers

Biomarkers of renal obstruction may reflect the response of the kidney in a direct manner, such as expression of growth factors that contribute to fibrosis or are associated with increased apoptosis in renal epithelium. They may also be downstream effects reflecting specific alterations mediated by other cytokines and not directly relevant but indicative of the level and pattern of the obstructive effect. An emerging broad approach, proteomics, uses assessment of changes in overall protein expression in the urine. Normal developing kidneys have an evolving protein fingerprint, which can be defined (Lee et al., 2008) and is altered with obstruction. If particular elements of the alteration can be identified and associated with clinical outcomes, these patterns may be diagnostic of functionally significant obstruction. Such patterns may reflect a single protein, which may be an element of a response pattern, or a downstream consequence (Chevalier, 2016; Jianguo et al., 2014; Li et al., 2018; Taranta-Janusz et al., 2013, Tian et al., 2015, Zhao et al., 2016). It may be that a particular pattern of protein expression, involving several factors, will be the best indicator of obstruction (Chevalier, 2016; Decramer et al., 2006, 2008; Stodkilde et al., 2013). Such studies will require development in animal systems and validation in the human. It will be necessary to set limits for what is and is not clinically significant "obstruction" and correlate this with clinical and functional outcomes of relevance. These changes must be correlated with histopathological changes in the developing kidney or more precise measures of renal function.

Diagnostic Imaging

Because the clinical presentation of the patient with urinary tract obstruction can be so variable, prompt and accurate diagnosis of obstruction is dependent on appropriate imaging. A review of the imaging modalities currently available and their advantages and limitations are presented later.

Ultrasonography

Renal ultrasonography remains a first-line imaging modality in the evaluation of a patient suspected of having urinary tract obstruction because of its availability, low cost, and lack ionizing radiation. It also does not require the administration of iodinated contrast and can therefore safely

be performed in patients with renal insufficiency or a contrast allergy. The renal ultrasound primarily provides anatomic information about the kidney including renal size, cortical thickness, corticomedullary differentiation, and the grade of collecting system dilation. **Although the presence of hydronephrosis is suggestive of underlying obstruction, it is important to recognize that hydronephrosis is an anatomic finding, not a functional diagnosis, and that hydronephrosis alone does not indicate urinary tract obstruction.** Significant hydronephrosis can be present in the absence of obstruction (e.g., in the patient with vesicoureteral reflux) and significant obstruction can be present in the absence of severe hydronephrosis, as is often the case very early in the course of acute renal obstruction. Parenchymal thinning and a small renal size can be evidence of chronic renal obstruction, and bladder distention in association with hydronephrosis can be suggestive of bladder outlet obstruction. **Standard renal sonography may appear normal in 50% of patients with acute urinary obstruction, and distinguishing obstructive from nonobstructive collecting system dilation can be difficult, especially when the obstructing agent is not visualized** (Mostbeck et al., 2001; Platt et al., 1989).

The introduction of duplex Doppler sonography was subsequently suggested as a means to improve the ability of ultrasonography to diagnose renal obstruction in patients. In the early 1990s, changes in intrarenal arterial waveforms were shown to be associated with urinary obstruction, and the resistive index (RI) (defined as the peak systolic velocity-end diastolic velocity/peak systolic velocity) was advanced as a technique to improve our detection of urinary obstruction during ultrasonography. After a short period of prostaglandin-mediated vasodilation, renal blood flow decreases and there is an increase in renal vascular resistance in response to obstruction. In general, an RI of 0.70 is considered to be the upper limits of normal in adults (Tublin et al., 2003), although important exceptions to this value have been reported. It is common for the mean RI to exceed 0.70 in children in the first year of life and can exceed 0.70 for at least the first 4 years of life. The RI can also exceed 0.70 in elderly patients without renal insufficiency. Initial clinical studies evaluating the RI threshold of 0.70 in the diagnosis of obstruction were encouraging, with a 92% sensitivity and 88% specificity. The diagnosis of obstruction increased further when the difference in RI (δ RI) between the affected kidney and contralateral kidney was found to be greater than 0.1 (Platt et al., 1989).

Although a number of encouraging studies evaluating RI have been reported, subsequent clinical trials and animal studies investigating RI in the detection of renal obstruction have been discouraging. Chen et al. (1993) demonstrated that the RI is normal in most patients with partial or mild obstruction. Similarly, when discriminatory thresholds for obstruction (mean RI ≥ 0.7, delta RI ≥ 0.1) were used in the detection of patients with acute renal colic, the sensitivity and specificity of the Doppler examination was found to be only 44% and 82%, respectively (Tublin et al., 1994). It has subsequently been demonstrated that radio-contrast can induce vasoconstriction and increase RI during Doppler sonography (Hetzel et al., 2001) and that nonsteroidal anti-inflammatory drugs (NSAIDs) can significantly decrease the RI of acutely obstructed kidneys (Shokeir et al., 1999), both of which may have been factors confounding the results of clinical studies investigating RI in the diagnosis of renal obstruction. Despite these observations, however, there has been increased skepticism over the utility of RI to detect renal obstruction (Gurel et al., 2006), and with widespread acceptance of non-contrast computed tomography (CT) scanning as the gold standard in the detection of renal calculi, the routine use of RI analysis in the evaluation of possible renal obstruction has declined.

Color Doppler ultrasonography has been shown to reliably identify ureteric jet dynamics in the bladder, and this has evolved as another diagnostic tool to distinguish obstructive from nonobstructive hydronephrosis. Burge et al. (1991) demonstrated that there was a significant decrease in the frequency of ureteral jets in patients with obstructing ureteral stones as compared with the normal ureter. More recently, Jandaghi et al. demonstrated that there is a significant decrease in the frequency, duration, and peak velocity of urine jets emanating from the obstructed ureterovesical junction when compared with the contralateral side, and differences of 1.5 jets/min, 2.5 s, and 19.5 cm/s in ureteral jet frequency, duration, and peak velocity, respectively, were proposed as cutoff points between obstructed and normal ureters (Jandaghi et al., 2013). de Bessa et al. (2008) evaluated the frequency of urine jets in children that had obstructive vs. nonobstructive hydronephrosis and demonstrated that a relative jet frequency (RJF = jet frequency of the hydronephrotic side divided by the sum of both ureteral jets over 5 min) of less than 25% had a sensitivity of 87% and a specificity of 96% in detecting obstruction. **Although the analysis of ureteral jets is easily applied during routine ultrasonography and may offer some valuable insight into the presence of obstruction, it does require good hydration of the patient and is limited by the requirement of a normal contralateral collecting system for comparison.**

Quantitative image analysis of renal ultrasounds with hydronephrosis has introduced the potential for more precise delineation of clinically significant hydronephrosis to better define patients needing more complex imaging (Cerrolaza et al., 2016; Kern et al., 2017).

One of the most common causes of urinary tract obstruction is the presence of renal or ureteral calculi. Although ultrasonography does not have the sensitivity of CT in detecting stones, it avoids the cumulative radiation dose from CT and can reveal secondary effects of urolithiasis, including hydronephrosis, infection, or abscess formation. It also has the advantage of detecting radiolucent stones. Ultrasound may detect calculi as small as 0.5 mm under optimal conditions, and stones typically manifest on ultrasound as echogenic foci in the collecting system associated with acoustic shadowing. Use of the twinkling artifact (TwA), an intense alternating color signal behind calcifications and stones, appears to be very useful in detecting stones smaller than 5 mm on ultrasound with a reported sensitivity of 99.12% and specificity of 90.91% (Gliga et al., 2017). **In a pooled analysis, ultrasound was demonstrated to have only a 45% sensitivity and 94% specificity in detecting ureteral stones and a 45% sensitivity and 88% specificity in detecting renal calculi as compared with noncontrast CT** (Ray et al., 2010)**. However, a recent multicenter comparative effectiveness trial demonstrated no difference in serious adverse events, pain scores, return emergency department visits, or hospitalizations when using ultrasonography versus CT for the initial evaluation of suspected nephrolithiasis** (Smith-Bindman et al., 2014)**. It has been shown that ultrasound overestimates renal stone size as compared with CT, particularly for stones 5 mm or smaller** (Sternberg et al., 2016)**, and this may have a significant impact on clinical decision making and counseling decisions** (Ganesan et al., 2017). Direct visualization of stones can be difficult on ultrasound because of the presence of overlying bowel gas and the relative depth of the ureter within the pelvis and can be further complicated in obese patients with large amounts of intervening fat (Cheng et al., 2012). **Because of these limitations, ultrasound is primarily used as a first-line investigative tool in pediatric and pregnant patients but can be used for routine follow-up in all patients with urolithiasis.**

Nuclear Renography

Nuclear medicine plays a critical role in the evaluation of the patient with possible urinary tract obstruction because it is the only imaging modality

that can provide noninvasive information about dynamic renal function. The nuclear study of choice in the evaluation of the obstructed collecting system is diuretic renography, most commonly performed using the radiopharmaceutical technetium-99m-mercaptoacetyltriglycine (^{99m}Tc-MAG3). **^{99m}Tc-MAG3 is preferred for diuretic renography because it has high extraction by the kidneys, rapid clearance, low radiation dose, and tubular secretion.** Renal uptake is 55% compared with 20% uptake by technetium-99m-diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA), the other radiopharmaceutical used for diuretic renography, resulting in better cortical imaging for qualitative and quantitative analysis (He and Fischman, 2008). **As opposed to ^{99m}Tc-MAG3, which is actively secreted by the tubules, ^{99m}Tc-DTPA is removed almost exclusively by glomerular filtration and is therefore the agent most suited to measurement of GFR. Adequate imaging of the collecting system, however, is GFR-dependent with DTPA and is limited in patients with renal insufficiency and those less than 6 months of age because of the immaturity of renal function.**

The normal renogram curve has three distinct phases. The initial phase is characterized by rapid uptake of the radiopharmaceutical by the kidneys reflecting renal perfusion. The second phase is characterized by a more gradual rise in uptake over time, usually peaking after 2 to 5 minutes. It is during the second phase that renal function is primarily evaluated. Urinary obstruction can diminish the rate of uptake of the radiotracer during the second phase and can therefore alter the assessment of differential renal function. The third phase is the excretory phase and is characterized by a gradual decrease in renal counts over time. The third phase is often augmented by the administration of a diuretic (diuretic renogram) to induce high urine flow and prevent the false-positive results that can be caused by urine stasis in a dilated collecting system. **By convention, a kidney is considered unobstructed if the T1/2 (time for one half of the tracer to leave the collecting system) is less than 10 min, is equivocal if the T1/2 is 10 to 20 min, and is considered obstructed if the T1/2 is greater than 20 min.** False-positive results can be seen in the presence of dehydration because of the suboptimal response to diuretic, poor renal function, high-grade reflux, and in the presence of massive collecting system dilation with urinary stasis (Goldfarb et al., 2006). Renal immaturity in neonates may also generate false-positive results (Karam et al., 2003).

To improve the accuracy of diuretic renography and limit false-positive results, patients should be well hydrated for the study. The well-tempered renogram was originally described for children in 1992 as a means to ensure a standardized level of hydration with the administration of IV fluids before and during the course of the study (Conway and Maizels, 1992). Bladder distention and elevated bladder pressures can limit the ability of the upper urinary tract to drain and may artificially prolong the excretory phase of the study. Routine catheter placement is therefore recommended for any patient who is unable to urinate voluntarily and should also be considered for any patient with significant reflux, bladder pathology (i.e., neurogenic bladder), or a low-lying pelvic kidney from which the signal may be obscured by bladder filling. Patient position during the study also appears to affect results, and urine flow may be slow and resemble obstruction when the patient is supine. It is therefore suggested that a later static image be obtained in any patient with prolonged T1/2 after they have assumed an upright gravity-assisted posture (Wong et al., 2000).

Timing of diuretic administration is somewhat controversial, and multiple different protocols have been established. Traditionally, furosemide is injected 20 minutes after the radiopharmaceutical is administered (F+20), although the diuretic can be administered 15 minutes before tracer injection (F−15) or at the time of tracer injection (F+0). The advantages of the F+20 technique are that the modifications to the drainage curve caused by furosemide can be observed, and if adequate kidney washout has occurred during the basic renogram, one can potentially avoid the administration of furosemide (Piepsz, 2011). With earlier administration of furosemide (F−15, F+0), urine flow is increased dramatically throughout the entire study; Turkolmez et al. (2004) found that these protocols allowed clarification of obstruction in cases of equivocal F+20 studies. The disadvantage of the F+0 protocol is that early furosemide injection can result in acceleration of renal transit and an underestimation of renal function on the side with a short transit time (Donoso et al., 2003). A recent study suggested improved results when patients were placed in a seated position and furosemide was administered 10 minutes after the radiopharmaceutical (F+10) (Tartaglione et al., 2013). **It is important to keep in mind that measurement of differential renal function and tracer washout varies depending on the protocol and radiopharmaceutical used, and care should be taken when interpreting results if comparative studies have been performed using different protocols or radiopharmaceuticals.**

Computed Tomography

Cross-sectional imaging provided by CT generates greater anatomic

definition than ultrasonography, and because of its speed, safety, and accuracy, noncontrast helical CT (NCHCT) has become the imaging modality of choice for patients suspected of having ureteral obstruction. In a landmark study, Smith et al. (1995) demonstrated the superiority of unenhanced helical CT in the evaluation of possible ureteral obstruction compared with excretory urography. Unenhanced helical CT gives information about obstructing and non-obstructing stones, and it can reveal signs associated with ureteral obstruction even after stone passage, including hydronephrosis, perinephric stranding, and the "tissue rim sign." These secondary signs have been reported to have a positive predictive value of more than 90% for the presence of acute ureteral obstruction (Heneghan et al., 1997; Smith et al., 1996). **CT has a reported sensitivity of 96% for stone detection with a specificity and positive predictive value of 100%** (Worster et al., 2002) **and can detect most radiolucent stones with the exception of protease inhibitor stones (e.g., indinavir sulfate) and mucoid matrix stones.** In addition, NCHCT has been demonstrated to diagnose a wide spectrum of significant and alternative diagnoses in 10% of patients evaluated for renal colic (Katz et al., 2000).

Although the unenhanced helical CT is the modality of choice in the evaluation of patients with acute renal colic, it has a limited ability to evaluate chronic obstruction of the urinary tract and various causes of obstruction other than calculi. Over the past decade, **multidetector computed tomography urography (CTU) has emerged as the imaging modality of choice for a comprehensive evaluation of the urinary tract** (Washburn et al., 2009). The traditional CTU technique involves three imaging phases using a single intravenous bolus injection of contrast. An unenhanced phase is initially performed followed by a nephrogenic phase obtained approximately 100 to 120 seconds after contrast injection, and an excretory phase is performed after a greater time delay to evaluate the urothelium. With the advent of improved software and high-resolution thin-slice CT scanning, three-dimensional (3D) reconstruction of the urinary tract can be performed and has been helpful in characterizing many obstructive lesions of the urinary tract. In addition to stones, calyceal diverticulum, crossing vessels causing UPJ obstruction, duplication anomalies in nonfunctioning systems, ureteroceles, and ectopic ureteral insertions can be visualized with good accuracy.

The primary concern regarding widespread use of CT is its associated high radiation exposure. The average mean effective dose for a single unenhanced CT has been reported to be 8.5 millisieverts (mSv) (Poletti et al.,

2007) **for a multidetector CT compared with 6.5 mSv for a single detector CT and 1.5 mSv for an excretory urogram series** (Katz et al., 2006). This dose can rapidly accumulate if there are multiple phases to the CT or the patient presents repeatedly. It has been estimated that the risk of fatal cancer is 0.05% or 1 in 2000 for 10 mSv of ionizing radiation (Brenner et al., 2001). **In children, the risks are more concerning because they are more sensitive to radiation-induced carcinogenesis and have a longer period of time for cancer to develop.** A recent study demonstrated that children receiving a cumulative brain dose of 50 mGy or more from CT had a 2.8 times higher risk of developing brain cancer and those receiving a cumulative bone marrow dose of 30 mGy or more from CT had a 3.2 times greater risk of developing leukemia (Miglioretti et al., 2013; Pearce et al., 2012). Because of these risks, low-dose protocols have emerged with very little loss in diagnostic accuracy (Poletti et al., 2007; Sade et al., 2017). Stones smaller than 3 mm, impaction at the UVJ, and patient obesity, however, have been shown to impair diagnostic accuracy of low-dose techniques (Kennish et al., 2010).

Magnetic Resonance Urography

Magnetic resonance urography (MRU) is an imaging modality that integrates excellent anatomic information with functional data and avoids ionizing radiation. Because of its significant cost and restricted availability, it is not a first-line imaging modality in the evaluation of a urinary obstruction at this time, but because of its major advantages over conventional imaging, MRU has the potential to become the imaging study of choice for the evaluation of urinary tract abnormalities in the future. The MRU protocol begins with standard T1- and T2-weighted imaging through the abdomen and pelvis without contrast. Gadolinium-diethylenetriaminepentaacetate dimeglumine (Gd-DTPA) is then administered in conjunction with furosemide, and T1-weighted imaging is performed allowing visualization of the concentrating and excretory functions of the kidney. MRU measurements of differential renal function and contrast excretion have been shown to correlate well with DTPA nuclear scintigraphy (Perez-Brayfield et al., 2003), but MRU has the advantage of providing excellent anatomic visualization of even nonfunctioning renal moieties. **The MRU measurement of contrast excretion is the renal transit time (RTT), which is defined as the time it takes for contrast to pass from the renal cortex to the proximal ureters. It is classified as normal if it is 4 min or less, equivocal if between 4 and 8 min, and obstructed if 8 min or longer** (Jones et al., 2004)**.**

Although the potential for MRU in pediatric obstruction is promising, the clinical correlation of these parameters to conventional diuretic renography and clinical outcomes remains to be defined, however (Grattan-Smith et al., 2011)**.** El-Nahas et al. (2007) reported that MRU has 100% sensitivity in diagnosing upper urinary tract obstruction, and MRU is valuable in diagnosing urinary tract abnormalities when traditional imaging is inconclusive (Payabvash et al., 2008). **Unfortunately, MRU detection of renal and ureteral stones is poor in comparison with CT because of the fact that stones appear as signal voids on T1- and T2-weighted images.** MRU sensitivity for detecting stones has been reported to be 68.9% to 84% (Blandino et al., 2001; Semins et al., 2013; Shokeir et al., 2004), but accuracy is greatly improved with gadolinium-enhanced excretory MRU, with sensitivities approaching 90% to 100% (Cerwinka and Kirsch, 2010). **The biggest risk of MRI is the development of nephrogenic systemic fibrosis (NSF), which was linked to gadolinium-based contrast agents in 2006 and appears to occur only in patients with severe renal impairment** (Thomsen, 2006). The incidence of NSF in patients with risk factors has been demonstrated to be 3% and current recommendations now limit the use of gadolinium in patients with renal impairment (Cerwinka and Kirsch, 2010). Newer agents may be able to reduce the risk of systemic fibrosis (Beam et al., 2017; Schieda et al., 2018; Soares et al., 2017).

Excretory Urography

Excretory urography (EXU) was previously considered the imaging modality of choice in the evaluation of patients suspected of having urolithiasis and/or urinary tract obstruction. Although it has largely been replaced with CTU, it does provide anatomic and functional information and can be useful in certain clinical situations. **Imaging during EXU is dependent on glomerular filtration and renal excretion of iodinated contrast medium; therefore the utility of excretory urography is limited in patients with renal insufficiency. The risk of contrast nephropathy also increases with worsening renal function. Excretory urography should not be performed in patients with a history of contrast allergy or those in whom radiation exposure is a concern (i.e., pregnancy).** A delay in contrast uptake and excretion by the kidney (delayed nephrogram) can be indicative of urinary tract obstruction, and the subsequent opacification of the collecting system with contrast can be helpful in identifying the level and potentially the source of obstruction. In addition, small renal size, parenchymal thinning, calyceal clubbing, and significant ureteral dilation and tortuosity can be signs of chronic urinary tract obstruction.

Whitaker Test

The Whitaker test, first described in 1973, is a urodynamic evaluation of the upper urinary tract that is helpful in differentiating an obstructed collecting system from an unobstructed hydronephrotic collecting system (Whitaker, 1973). Renal scintigraphy can give false-positive results in the face of massive collecting system dilation or poor renal function, because continued filling, rather than drainage, of the collecting system occurs in response to furosemide leading to an apparent prolongation in the calculated washout time. **The Whitaker test involves placement of a percutaneous needle in the collecting system of the kidney and the infusion of contrast at a rate of 10 mL/min. A urodynamic catheter is also placed in the bladder and intravesical pressures are monitored and subtracted from measured intrapelvic pressures during the infusion.** Intrapelvic pressures are noted at the time that contrast is first seen extending past the UPJ and past the ureterovesical junction (UVJ). **Pressures less than 15 cm H_2O are considered normal, greater than 22 cm H_2O is indicative of obstruction, and between 15 and 22 cm H_2O is considered indeterminate.** Although the reproducibility and clinical utility of the Whitaker test has been questioned (Djurhuus et al., 1985), the test has recently been shown to determine or contribute to therapeutic management in 84% of cases of suspected obstruction and to accurately predict obstruction and non-obstruction in 77% of cases (Lupton and George, 2010). A study by Veenboer et al. in 2011 demonstrated a 100% negative predictive value in the ability of the Whitaker test to diagnose the absence of obstruction. **Although the Whitaker test has limited applicability in clinical practice, it continues to have a role in the evaluation of equivocal upper urinary tract obstruction, especially when noninvasive investigations are inconclusive.**

Retrograde Pyelography

Retrograde pyelography refers to the injection of contrast into the upper collecting system through a cystoscopic approach. The technique accurately defines ureteral and upper collecting system anatomy and can determine the location of an obstructive lesion. It is most often used to define the anatomy of the collecting system when it has not been adequately defined by other imaging modalities or when a patient has risk factors for receiving iodinated contrast material. It may also provide more specific insight into the anatomy of the ureter and renal pelvis to better plan the surgical approach. Because retrograde pyelography involves intubation of the ureter with a catheter, bacteria may be introduced into the upper urinary tract during the procedure. The technique is therefore associated with an increased risk of UTI/sepsis in the setting of obstruction if the collecting system is not subsequently drained.

Antegrade Pyelography

Antegrade pyelography is most often used when retrograde pyelography is not technically feasible or when other imaging studies do not adequately define the collecting system.

Key Points: Imaging of Obstruction

- Hydronephrosis is an anatomic finding, not a functional diagnosis, and hydronephrosis alone does not indicate urinary tract obstruction.
- Ultrasound has a limited sensitivity in detecting stones, particularly ureteral stones, as compared with noncontrast CT.
- Ultrasound overestimates renal stone size as compared with CT, particularly for stones 5 mm or smaller, and this may have a significant impact on clinical decision making and counseling decisions. Ultrasound is primarily used as a first-line investigative tool in pediatric and pregnant patients but can be used for routine follow-up in all patients with urolithiasis.
- ^{99m}Tc-MAG3 is preferred for diuretic renography because it has high extraction by the kidneys, rapid clearance, low radiation dose, and tubular secretion.
- ^{99m}Tc-DTPA is removed almost exclusively by glomerular filtration and is therefore the agent most suited to measurement of GFR. Adequate imaging of the collecting system, however, is GFR-dependent with DTPA and is limited in patients with renal insufficiency and those less than 6 months of age because of immaturity of renal function.
- The primary concern regarding widespread use of CT is its high associated radiation exposure. In children, the risks are more concerning because children are more sensitive to radiation-induced carcinogenesis and have a

longer period of time for cancer to develop.

- MRU measurements of differential renal function and contrast excretion have been shown to correlate well with DTPA nuclear scintigraphy. Unfortunately, MRU detection of renal and ureteral stones is poor in comparison with CT because of the fact that stones appear as signal voids on T1- and T2-weighted images.
- The biggest risk of MRI is the development of NSF, which is linked to gadolinium-based contrast agents and appears to occur only in patients with severe renal impairment.

Pathological Changes of Obstruction

Pathological Changes in the Mature Kidney

The gross pathological changes that occur in the mature kidney in response to obstruction have been well described in animal models and parallel findings in humans. After 42 hours of obstruction, there is dilation of the collecting system and blunting of the papillary tips associated with an increased weight of the kidney. Collecting system dilation and renal weight further increase and the parenchyma becomes edematous after 7 days of obstruction. Further collecting system dilation develops after 12 days of obstruction, but after 21 to 28 days the cortex and medullary tissue in the obstructed kidney become diffusely thinned. After 6 weeks, the obstructed kidney is enlarged with a cystic appearance, but lower weight, as compared with the normal contralateral kidney (Ladefoged and Djurhuus, 1976).

The histologic derangements associated with early obstruction are localized primarily to the tubulointerstitial compartment of the kidney and include massive tubular dilation, progressive tubulointerstitial fibrosis, inflammatory cell infiltration, and apoptotic renal tubular cell death. Although the glomeruli of the kidney are relatively spared, damage to the tubulointerstitial compartment of the kidney is severe (Misseri et al., 2004; Nagle et al., 1973; Sharma et al., 1993). Inflammatory cell infiltration occurs early in the course of obstruction (Diamond et al., 1994, 1998) and results in the release of a variety of cytokines and growth factors that stimulate fibroblast proliferation and activation, and an imbalance in extracellular matrix (ECM) synthesis, deposition, and degradation. This results in an expansion of the interstitial space and a disruption in normal cellular communication (Fig. 40.2). Increasing tubular cell death accompanies progressive interstitial fibrosis (Docherty et al., 2006**), and long-standing obstruction ultimately results in glomerulosclerosis (Figs. 40.3 and 40.4), most likely as a result of chronic inflammation** (Steinhardt et al., 1988) **and/or hyperfiltration injury** (Pascual et al., 1998). Although extensive glomerulosclerosis has been shown to correlate well with a decrease in renal function in patients with obstruction, milder degrees of fibrosis and glomerulosclerosis can be seen in up to 25% of patients with obstruction and normal differential function on radionuclide imaging (Elder et al., 1995).

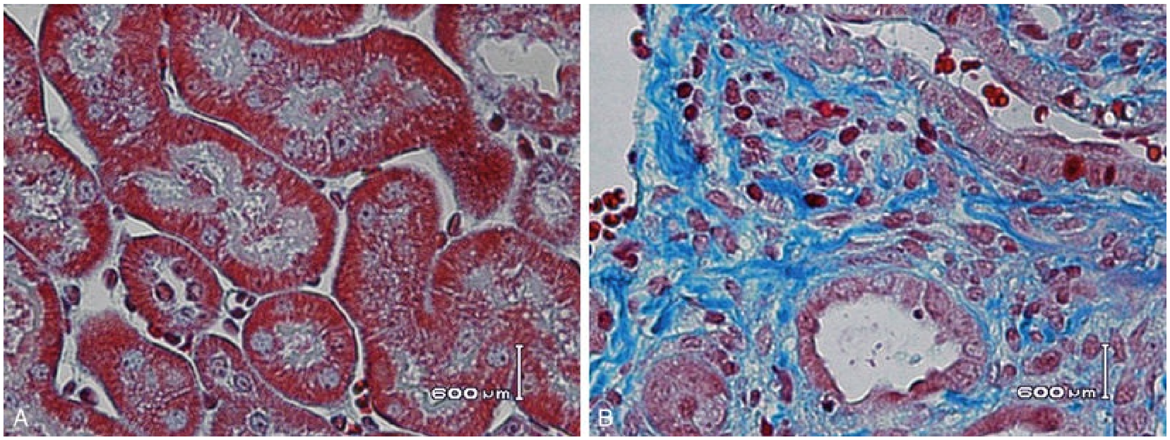

FIG. 40.2 Masson trichrome stained tissue sections from a mouse kidney exposed to sham operation (A) or 2 weeks of unilateral ureteral obstruction (B). Staining depicts significant collagen deposition *(blue)* and expansion of the interstitial space in response to obstruction.

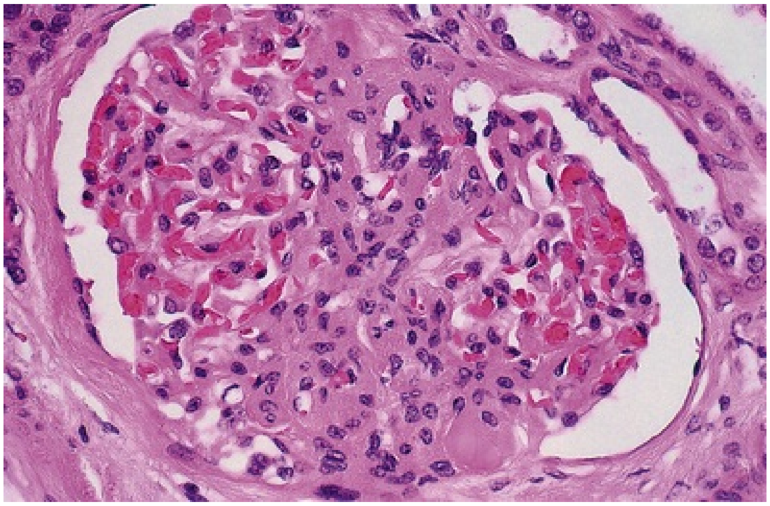

FIG. 40.4 Sections of deep cortex and outer medulla from a patient with chronic obstructive uropathy. Glomerulus with segmental tuft sclerosis *(center)* and hyalinosis is seen. Hematoxylin and eosin stain; original magnification, ×100. (Courtesy Dr. Sami Iskandar.)

Pathological Changes in the Developing Kidney

General Observations

The pathological correlates of congenital obstruction have been described to varying degrees (Elder et al., 1995; Han et al., 1998; Huang et al., 2006; Poucell-Hatton et al., 2000; Stock et al., 1995; Zhang et al., 2000). The pathological changes associated with lesser degrees of obstruction have been less thoroughly investigated, and a spectrum of qualitatively similar alterations have been described. In the absence of overt functional alterations and in unilateral conditions, determining the state of the one affected kidney becomes a clinical challenge.

Histologic examination of obstructed renal tissues has shown disorganization of structure with primitive forms of renal tissues, pathologically defined as dysplasia. Although the definition of dysplasia is not universally agreed upon, evidence of altered renal development in association with obstruction is frequently reported (Bernstein, 1971; Matsell, 1998; Matsell and Tarantal, 2002; Matsell et al., 2002; Peters et al., 1992; Tarantal et al., 2001). Dysplasia is often considered to be an embryonic process and irreversible. It is clear that some dysplasias are due to very early abnormalities of renal development (Winyard and Chitty, 2008) and unrelated to obstruction, but it is equally clear that obstructive processes can produce dysplasia. In some cases, however, usually in lesser degrees of obstruction, there is no dysplasia (Bonsib, 1998; Zhang et al., 2000).

If obstruction can produce dysplasia or abnormal developmental patterns, the character of these alterations may provide insights into the critical mechanisms of obstructive nephropathy. **Development is the controlled process of growth and differentiation of tissues in the formation of an organ or tissue. The factors that regulate these processes are likely targets of obstructive effects.**

Structural alterations with obstruction are obviously evident with hydronephrosis, but this is largely a distortion of normal architecture and relative alterations in the amounts of elements of renal tissues. There may be subtle changes, however, that are functionally important. Other alterations include fibrosis and increased interstitial tissues, as well as the presence of abnormal tubules and glomeruli. The normal layered organization of the kidney with the cortical and medullary areas with inner and outer stripes is often distorted or absent (Zhang et al., 2000). Less obvious are changes in the differentiation of the individual renal cell types that make up the nephron (Huang et al., 2006). Cells are unlikely to perform their normal functions, including communicating with neighboring cells in an integrated fashion. Function may therefore be disrupted.

Closely tied with these altered patterns of structure are distortions of normal growth regulation with either increased or decreased growth of specific structures. In some cases, obstructed kidneys are markedly smaller than normal, and in a developmental context, this does not represent atrophy but hypoplasia. The distinction is important in that renal tissue mass has not been lost but has never been formed. This is growth failure, not atrophy, and the mechanisms are likely distinct.

These observations are supported by clinical and experimental work. Several biopsy studies have shown patterns indicative of altered differentiation and growth in various levels of obstruction, including upper (UPJ obstruction) (Elder et al., 1995; Huang et al., 2006; Stock et al., 1995; Zhang et al., 2000) and lower (posterior urethral valves) (Haecker et al., 2002; Poucell-Hatton et al., 2000). These variations are not well explained and correlation with clinical parameters is imperfect. Experimental studies, however, have shown that obstruction during development will produce changes in patterns of renal differentiation and in growth regulation (Beck, 1971; Cachat et al., 2003; Gonzalez et al., 1990; Mure et al., 2006; Peters et al., 1992; Steinhardt et al., 1988; Wen et al., 2002). These can be seen to vary depending upon the time of onset in experimental models, as well as the severity of obstruction (Chevalier et al., 1988, 1999a,b; Klein et al., 2011; Thornhill et al., 2005; Truong et al., 2011). The latter is difficult to measure accurately. The validity of any of these model systems must be considered conditional, however, until we have more definite correlations. Nonetheless, it is clear that induced obstruction can produce such severe abnormalities of differentiation as to be considered dysplasia and to produce clear disruptions of growth regulation (Peters et al., 1992). It is therefore reasonable to examine the specific patterns observed and the potential mechanisms of those changes, all of which are likely contributing factors in the development of obstructive nephropathy.

The effects of obstruction on the developing kidney may be summarized as producing alterations in the regulation of growth, tissue differentiation, extracellular matrix, and fibrosis, and in altering the functional integration of the kidney. The latter is largely a result of the first three major factors and refers to the mechanisms producing vascular, neural, and humoral homeostasis and in the regulation of inflammatory cascades. Understanding the mechanisms by which these systems are dysregulated by obstruction will permit a better understanding of the outcomes of obstruction, which should improve our diagnostic, prognostic, and therapeutic abilities.

Growth

Growth regulation is a critical part of development, and the obstructed kidney may demonstrate impaired or accelerated growth. It is important to recognize that the small, obstructed kidney is not atrophic as may be seen in the adult, but it is hypoplastic. The growth it should have experienced never occurred. This can be readily seen by prenatal ultrasound and has been shown repeatedly experimentally (Mandell et al., 1994; Peters et al., 1992). This seems to usually be a generalized impairment of all parts of the kidney, with reduced numbers of nephrons as well as smaller nephrons. Differential growth impairment within the nephron segments may be present as well (Cachat et al., 2003; Huang et al., 2006). The functional effects of significant growth impairment are obvious because there are fewer and smaller nephron units. There may be compensatory responses to these changes, and it is difficult to assess their long-term impact. Reduced renal mass can be associated with hypertension as well as reduced filtration function, and loss of tubular mass will affect electrolyte and acid-base homeostasis, as well as water balance.

Growth acceleration can be seen in the larger-than-normal hydronephrotic kidney, although this is difficult to prove in humans, as few of those kidneys are removed. In animal experiments, fetal partial obstruction can increase renal mass (Ayan et al., 2001; Gobet et al., 1999). This is not seen with dysplastic changes and is not a product of edema because the total protein and DNA are increased as well. The factors that predict altered growth appear to be the severity of obstruction and timing of the obstructive effect, although the latter is difficult to ascertain in human situations. The functional consequences of accelerated growth are not known, and this may correlate with the occasional hyperfunction measured on renal scans that is seen in some patients with hydronephrosis (Maenhout et al., 2005; Moon et al., 2003). Compensatory responses to obstruction may not be benign; growth enhancement of the glomeruli occurs in early diabetes and is later associated with glomerular sclerosis.

Growth Regulation of the Kidney.

Regulation of renal growth is extremely complex and dynamic through development. A variety of growth factors are known to influence kidney growth at various stages of renal development and act at different loci of the nephron. Obstructive conditions have been shown to alter expression of growth-regulatory genes as well as the presence of the proteins coded by these genes (Chevalier, 1996). Table 40.1 lists some of the factors reported to be altered in renal obstruction (not all in early or fetal models) and potentially important mechanistic determinants. EGF has been shown to reduce some of the growth effects of obstruction when administered exogenously (Chevalier et al., 1998, 1999; Kennedy et al., 1997; Wen et al., 2009). Many studies have focused on specific growth factors, but it is evident from the complexity of renal development and growth regulation that the interactions of multiple factors and their signaling pathways will be of greater relevance.

TABLE 40.1

Key Factors in Congenital Obstructive Uropathy

APOPTOSIS ACTIVATION	APOPTOSIS INHIBITION
GROWTH	
TGF-β1 (Ayan et al., 2001; Medjebeur et al., 1997)	BMP7 (Klahr and Morrissey, 2002) HGF (Liu, 1999)
RAS (Eskild-Jensen et al., 2007): AT1 receptor	Angiotensin AT2 receptor (Liapis, 2003; Ma et al., 1998)
TNF-α/NF-κB (Misseri et al., 2005; Meldrum et al., 2006)	STAT6 (Yukawa et al., 2005a)

BAD, Bax (Liapis, 2003)	Bcl-2 (Manucha et al., 2007; Manucha and Valles, 2008)
ROS (Ricardo et al., 1997)	Catalase, SOD (Kinter et al., 1999; Truong et al., 2011)
DAPK (Yukawa et al., 2005b)	CD44 (Rouschop et al., 2004)
Tubular stretch (Cachat et al., 2003; Nguyen et al., 2000)	EGF (Chevalier et al., 1999; Bartoli et al., 2000, 2011; Grandaliano et al., 2000)
p53 caspases (Choi et al., 2000; Guerin et al., 2008; Misseri et al., 2005; Nguyen et al., 2006)	P21 (Silverstein et al., 2003)
FAS (Choi et al., 2000)	HO-1 (Kim et al., 2006; Li et al., 2012)
NHE1 downregulation (Manucha et al., 2007)	HB-EGF (Nguyen et al., 2000)
	IGF (Kiley et al., 2003)
	Osteopontin (Yoo et al., 2006)
	PAX2 (Cohen et al., 2007)
	SS-31 (Mizuguchi et al., 2008)
EMT INDUCTION	**EMT INHIBITION**
DIFFERENTIATION	
TGF-β1/Smad2/Smad3 (Chevalier, 2008; Inazaki et al., 2004)	BMP7 (Klahr and Morrissey, 2002)
Snail-1 (Yoshino et al., 2007)	ALK TGF-β1R inhibitor (Galarreta et al., 2013)
PAI-1 (Zhang et al., 2007)	
Leukocytes (Lange-Sperandio et al., 2007)	
Angiotensin (Topcu et al., 2007)	
PROFIBROTIC	**ANTIFIBROTIC**
FIBROSIS	
TIMPs (Ayan et al., 2001; Mure et al., 2006)	MMPs (Gobet et al., 1999a)

Apoptosis Regulation.

A critical component of growth in the developing kidney is apoptosis, regulated cell death. The early fetal kidney is extremely active in terms of

new cell formation as well as turnover (Carr et al., 1995)**. This permits remodeling during development, as well as providing a control system over unregulated growth.** Small increases in the rate of apoptosis, even with normal ongoing growth, would lead to significant reductions in renal mass over time. The role of apoptosis in congenital obstruction has become more firmly established in recent years, including cellular patterns characteristic of apoptosis and enhanced expression of apoptosis regulating molecules (Campbell et al., 2008; Eskild-Jensen et al., 2007; Klein et al., 2011; Yang et al., 2001; Yoo et al., 2006). The changes may be seen heterogeneously, and the precise means by which these alterations occur remains incompletely defined, although apoptotic activity is regulated by cytokines (Campbell et al., 2008; Cohen et al., 2007; Manucha and Valles, 2012; Manucha et al., 2007) as well as mechanical factors (Hsieh and Nguyen, 2005; Nguyen et al., 2000). Inappropriate apoptosis may also be related to interstitial fibrosis as well (Docherty et al., 2006). An important aspect of understanding the role of apoptosis in congenital obstruction is that the mediators may be measurable in the urine or blood, and they may permit therapeutic manipulation (Mizuguchi et al., 2008).

Differentiation

Differentiation is the process of cells attaining specific functional traits to permit specialized functions and organization into tissues and is the basis for the many functions of the kidney. Obstruction affects these finely tuned patterns by gross structural disruption as seen in a severely obstructed dysplastic kidney. More subtle effects may require assessment of tubular or glomerular function, but all are a result of altered differentiation. Disruption of differentiation may begin as early as induction of the nephron or later in development with injury to renal collecting duct cells that regulate urinary concentrating ability. Some of these changes may be reversible, but it is usually presumed that many are not. Some cells will undergo terminal differentiation, and if that does not occur at a particular time point in development, there will not be another opportunity for it to occur. Disruption of normal differentiation of renal elements is unique to congenital obstruction and does not occur in a major way in adult obstruction. Abnormal epithelial-to-mesenchymal transformation (EMT) is one alteration in differentiation that does occur in the adult and can be reversible (Docherty et al., 2006; Forino et al., 2006; Hay and Zuk, 1995; Higgins et al., 2007; Ivanova et al., 2008; Yang et al., 2005). A variety of mediators of EMT have been described, including TGF-β, plasminogen (Zhang et al., 2007), and leukocytes (Lange-Sperandio, Trautmann et al. 2007), as well as inhibitors, such as hepatocyte growth factor (HGF) (Yang et al., 2005; Fig. 40.5). It is likely to be an important factor in fetal obstruction as well, although little is known about its role. Most adult cells may be injured and lose their differentiated capacity, but the cell types rarely change their behavior once differentiated. Understanding the patterns of altered differentiation and its regulators is critical to understanding congenital obstructive nephropathy.

FIG. 40.5 Renal cellular interactions in obstructive nephropathy. The interstitium is infiltrated by monocytes, which are “classically” activated to macrophages that release cytokines such as TGF-β1 and tumor necrosis factor-α (TNF-α). In turn, TGF-β1 promotes a phenotypic response of tubular epithelial cells either to undergo apoptosis (leading to tubular atrophy) or to undergo epithelial-to-mesenchymal transition (EMT), becoming fibroblasts that migrate to the interstitium. Angiotensin II (ANG

II), produced by the activation of monocytes, stimulates the production of nuclear factor kappa B (NF-κB), which leads to the recruitment of more macrophages, as well as to the production of reactive oxygen species (ROS), which aggravates renal tubular injury. In contrast, alternatively activated macrophages can enhance tubular cell survival and proliferation. Endothelial cells can undergo endothelial-mesenchymal transition (EndMT) or apoptosis, which leads to capillary loss and secondary renal ischemia and hypoxia. Resident pericytes and infiltrating hematopoietic stem cells can also differentiate into fibroblasts. Under the stimulus of cytokines such as TGF-β1 produced by macrophages or other cells, fibroblasts synthesize stress fibers and undergo further differentiation to become myofibroblasts. The myofibroblasts are contractile and augment the deposition of extracellular matrix (ECM), leading to progressive interstitial fibrosis. This process is augmented by a decrease in ECM degradation, mediated by plasminogen activator inhibitor-1 (PAI-1) and tissue-type plasminogen activator (tPA). (From Chevalier RL, Forbes MS, Thornhill BA: Ureteral obstruction as a model of renal interstitial fibrosis and obstructive nephropathy. *Kidney Int* 75:1145–1152, 2009).

Induction Process.

Renal differentiation begins with induction and from then on is exquisitely sensitive to various outside effects that may disrupt the normal sequence of cellular changes that results in a kidney. When these may be disturbed by obstruction is unclear, but it can be presumed that some of the variation in the spectrum of obstruction is due to different times of onset of the obstructive effect and to different degrees of severity (Guo et al., 2015). The pattern of effect is likely to reflect the time of onset and be reflected in the number of nephron generations and the degree of dysplastic transformation. Controversy remains as to whether obstruction can produce dysplasia, and it is often stated that if dysplasia is present, then it was because of abnormal induction and not obstruction. Abnormal induction and nephrogenesis may be produced by various factors, including genetic ones, or because of cellular disruption from mechanical forces with subsequent cellular responses. The study of Berman and Maizels (1982) is often cited to indicate that dysplasia in the chick kidney (a mesonephric kidney) was produced only with mechanical disruption of the mesenchyme and not hydronephrosis. The production of “obstruction” in that elegant study was by necessity rather crude, and several of the preparations were not obstructed. It is unclear whether they all were to a sufficient degree. It also suggests that mechanical forces can, in fact, disrupt nephrogenesis enough to produce dysplasia, and there is no inherent reason to believe that this cannot be from obstruction as well. Later mammalian studies in fetal sheep have shown dysplastic changes produced by obstruction (Matsell et al., 1996; Peters et al., 1992; Steinhardt et al., 1988b), and this has been shown in rodent studies as well (Thomasson et al., 1970).

The critical determinant of dysplasia in animal studies has been complete obstruction early in gestation. In the fetal sheep dysplasia was only seen when the obstruction was induced before 50% of gestation (70 days in most sheep species, which have a gestation from 140 to 145 days). Obstruction induced after that point only produces hydronephrotic changes, albeit severe (Beck, 1971). Partial obstructions produced hydronephrosis only, without apparent disruption of the renal architecture. The reason for this is presumably altered sensitivity of the developing nephrons to obstructive effects at this point. Alternatively, the particular signaling systems that are active in the early phases of renal development begin to fade away with ongoing development. It is possible that the pathways sensitive to obstruction, which would inherently alter the pattern of development, have run their course of expression and activity by mid-gestation. Expression of recognized mediators of renal development have been shown to be affected in models of fetal obstruction, including *WT-1* (Liapis, 2003), *Wnt* gene family (Nguyen et al., 1999), and *PAX2* (Attar et al., 1998; Cohen et al., 2007; Fenghua et al., 2009; Galarreta et al. 2013; Manson et al., 2014, 2015a, 2015b; Mure et al., 2006; Wilhide et al., 2016).

One of the histologic hallmarks of renal dysplasia is fibromuscular collars surrounding tubular structures, so-called *primitive ducts*. These have a characteristic appearance, and the smooth muscle surrounding the tubules stains for α-smooth muscle actin (α-SMA) (Fig. 40.6). This pattern suggests an abnormality in the regulation of epithelial-to-mesenchymal transformation (Baum et al., 2008; Butt et al., 2007). The mesenchymal structures of the primitive nephrogenic blastema and the epithelium of the ureteral bud processes interact, and there is differentiation from an epithelial-to-mesenchymal phenotypes and the reverse. It is uncertain whether the presence of the primitive tubules suggests persistence of mesenchyme that should have transformed to epithelium, or inappropriate epithelial-to-mesenchymal transformation. Understanding the signaling pathways involved in these processes (Bani-Hani et al., 2008; Roberts et al., 2006) will directly affect our understanding of obstructive processes. Persistent expression of α-SMA can be seen in partial obstruction without dysplastic patterns and so may be important at several levels of severity (Gobet et al., 1999; Mure et al., 2006). α-SMA expression is regulated by TGF-β1, linking these two proteins to growth as well as fibrotic changes.

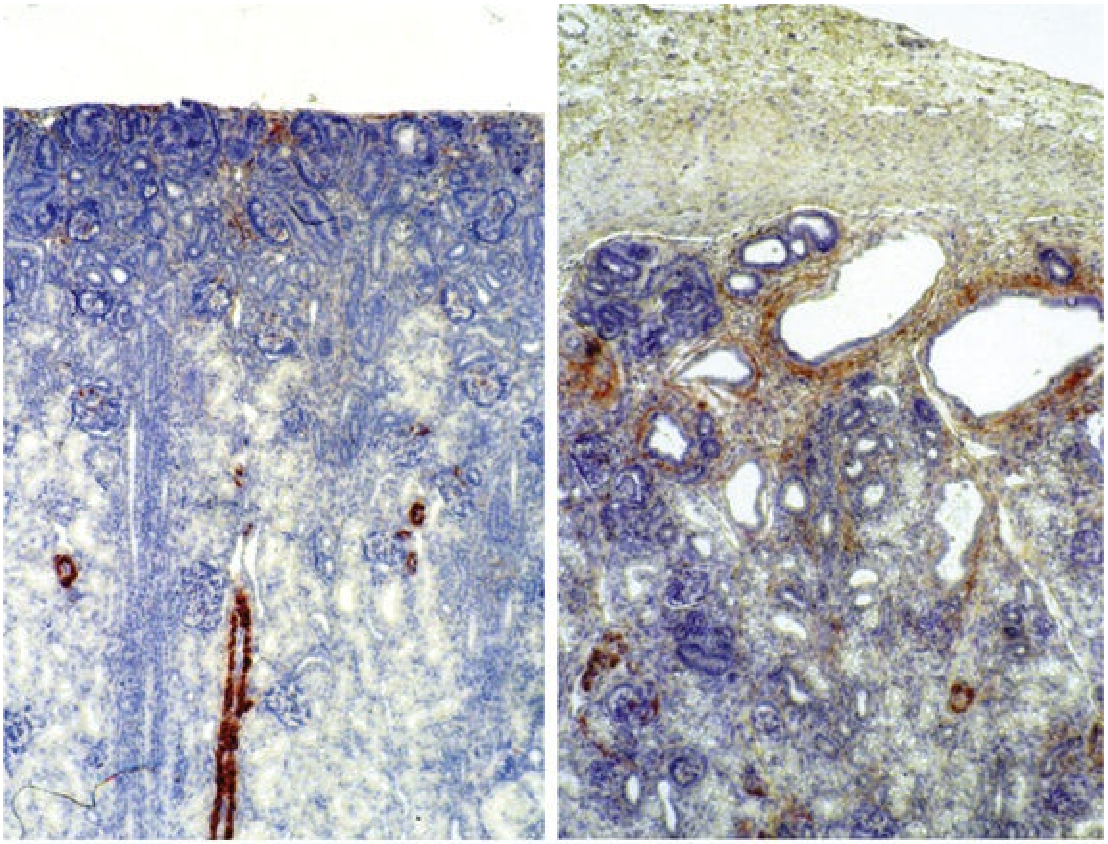

FIG. 40.6 Histologic view of normal and obstructed full-term sheep showing the abnormal structural pattern of the kidney, increased interstitial fibrosis and cells, as well as abnormally persistent α-smooth muscle actin (brown stain). (From Gobet et al.: Fetal partial urethral obstruction causes renal fibrosis and is associated with proteolytic imbalance. *J Urol* 162:854–860, 1999.)

Development of the glomerulus is a tightly regulated process that involves interaction of the mesenchyme and epithelium with a very specific pattern of growth and formation of intermediate structures such as the S-shaped body. In general, primitive glomeruli are not evident in obstructive changes, but markedly abnormal glomeruli are seen as well as hypoplastic glomerular structures (Matsell et al., 2002). In some cases, glomeruli may be enlarged in obstruction, suggestive of the changes seen in hyperfiltration that leads to glomerulosclerosis. Dissociation of the glomerulus from the tubules can be seen in early neonatal rodent obstruction (Thornhill et al., 2007), suggesting severe disruption of the developmental program.

Tubulointerstitial Fibrosis

Tubulointerstitial fibrosis is a major pathological component of obstructive renal injury. In response to kidney obstruction, pro-fibrotic signaling pathways are stimulated to increase production and deposition of extracellular matrix. This causes an expansion of the interstitial space, and ultimately, a disruption in the normal architecture of the kidney. As the tubulointerstitial space expands, intercellular signaling is disrupted and progressive renal dysfunction ensues. Progressive tubulointerstitial fibrosis is, in fact, a hallmark of all kidney diseases that lead to chronic renal failure (Zeisberg and Neilson, 2010).

Inflammatory Cell Infiltration

One of the earliest histologic changes in the obstructed kidney is an increase in inflammatory cell infiltration into the interstitial compartment of the kidney. Macrophage infiltration has been documented as early as 4 hours after the onset of renal obstruction (Schreiner et al., 1988), and the recruitment of macrophages, as well as other inflammatory cells, into the interstitial space appears to be mediated by chemokine production. All types of renal cells can express chemokines in response to immunologic, toxic, ischemic, or mechanical injury, and the interaction of chemokines with specific receptors expressed on immune cells (chemokine receptors) facilitates the migration of leukocytes and macrophages across the endothelium (Anders et al., 2003). The renin-angiotensin system has also been implicated in obstruction-induced inflammatory cell infiltration. Angiotensin II, a potent vasoconstrictor, is rapidly stimulated after the onset of renal obstruction, and studies have demonstrated that angiotensin II participates in the regulation of renal monocyte recruitment, primarily through interactions with the angiotensin II (AT2) receptor and the subsequent stimulation of the nuclear factor-kappa B (NF-κB) pathway (Esteban et al., 2004). NF-κB, in turn, stimulates the expression of chemokines (chemokine ligand 2 [CCL2] and chemokine ligand 5 [CCL5]) and adhesion molecules (vascular cell adhesion molecule-1 [VCAM-1] and intercellular adhesion molecule 1 [ICAM-1]) that facilitate monocyte recruitment (Klein et al., 2011).

Once inflammatory cells populate the interstitium, they begin to elaborate a wide array of proinflammatory cytokines and growth factors that contribute to renal injury, including tumor necrosis factor-α (TNF-α), interleukin-18 (IL-18), and TGF-β (Bani-Hani et al., 2009; Klahr and Morrissey, 2002; Misseri et al., 2004). Increased expression of chemokines has been demonstrated in response to obstruction, including monocyte chemotactic protein-1 (MCP-1 or CCL2), macrophage inflammatory protein-1α (MIP-1α or CCL3), macrophage inflammatory protein-1β (MIP-1β or CCL4), and CCL7, and blockade of CCL2 and CCL7 has further been shown to ameliorate obstruction-induced tubulointerstitial fibrosis (Bani-Hani et al., 2009; Gonzalez et al., 2013; Wada et al., 2004). Indeed, MCP-1 has recently been identified as a potential urinary biomarker of obstruction in children with hydronephrosis (Madsen et al., 2013). Although this inflammatory cell infiltrate is certainly critical to the pathophysiology of urinary tract obstruction, cytokines and proinflammatory mediators can also be produced by renal tubular epithelial cells independent of macrophage infiltration (Franke et al., 2012; Kaneto et al., 1996; Misseri et al., 2004). A variety of other potentially important molecular effectors of fibrosis have been investigated with the potential to therapeutically reduce the impact of fibrosis (Manson et al., 2015; Singh et al., 2016).

Interestingly, models of fetal kidney obstruction demonstrate little evidence of renal inflammation (Peters et al., 1992)**, and inflammatory infiltration is surprisingly sparse in biopsies of human kidneys with congenital obstruction and no history of infection** (Huang et al., 2006). Increased extracellular matrix is seen in fetal obstruction as well (Gobet et al., 1999). It has been demonstrated in animal models, however, that a marked inflammatory cell infiltrate associated with fibrosis is observed if fetal obstruction continues after birth (Mure et al., 2006). This suggests a fundamentally distinct mechanism in the pathophysiology of congenital obstruction as compared with postnatally acquired kidney obstruction. However, similar to postnatal renal obstruction, involvement of the renin angiotensin system is evident in fetal obstructive processes as well and may offer pathways for therapy (Ayan et al., 2001; Gobet et al., 1999; Singh et al., 2016). Although the inflammatory response probably does not have a significant role in the development of renal alterations during fetal life, the development of obstruction-induced inflammation in the newborn kidney may be influenced by the increased renal functional demand of postnatal life (Klein et al., 2011).

Elaboration of Growth Factors and Cytokines

Transforming Growth Factor-β1 (TGF-β1)

TGF-β1 has long been regarded as one of the most critical mediators of obstruction-induced renal injury. Renal TGF-β1 and TGF-β receptor expression increase in fetal and mature kidneys in response to obstruction (Chevalier et al., 2010; Kaneto et al., 1993; Yang et al., 2001)**, and evidence indicates that TGF-β1 is a major regulator of renal fibrosis via stimulation of EMT (a process by which epithelial cells undergo phenotypic transformation into matrix producing myofibroblasts), fibroblast proliferation** (Fan et al., 1999; Postlethwaite et al., 1987; Zeisberg et al., 2003)**, extracellular matrix synthesis (Roberts et al., 1992), and the simultaneous inhibition of collagenase and degradative matrix metalloproteinases** (Border and Noble, 1994; Chandrasekhar and Harvey, 1988). TGF-β1 is expressed by macrophage and resident tubular cells, and upon activation, TGF-β1 will bind to its receptor and stimulate the Smad family of proteins to multimerize into a transcription-regulating complex that translocates into the nucleus and exerts TGF-β1's biologic effects (Massague and Chen, 2000). Smad2 and Smad3 appear to mediate TGF-β1's profibrotic properties, whereas Smad7 is inhibitory and protects against renal fibrosis (Lan et al., 2003; Liu et al., 2017; Sato et al., 2003). It has been demonstrated that TGF-β1 induces proliferation of human renal fibroblasts in vitro by inducing the production and secretion of fibroblast growth factor 2 (FGF-2) (Strutz et al., 2001), and that a competitive inhibitor to the FGF-2 receptor, Klotho, prevents FGF-2–induced fibroblast proliferation and activation, and inhibits TGF-β signaling and obstruction-induced renal fibrosis (Doi et al., 2011; Guan et al., 2014). Several of these pathways have been shown to be present in fetal renal obstruction as well (Gobet et al., 1999a,b).

Bone morphogenic protein-7 (BMP7) is a member of the TGF-β superfamily that stimulates Smad1/5/8 activation and inhibits TGF-β dependent biologic functions after binding to its receptor BMPR1 (Meng et al., 2013); however, the mechanism by which BMP7 counteracts TGF-β activity remains unclear. Several studies have demonstrated that exogenous BMP7 cannot only inhibit TGF-β1–induced EMT and renal fibrosis but actually induce mesenchymal-to-epithelial transition in adult fibroblasts and facilitate regeneration of the injured kidney (Patel and Dressler, 2005; Zeisberg et al., 2005). The BMP7 pathway is activated after correction of renal obstruction, and activation of BMP7 during renal recovery promotes the resolution of fibrosis and the restoration of normal renal architecture (Manson et al., 2011). Although the downstream mechanisms that contribute to BMP7–mediated kidney repair remain unclear, BMP7 has promising therapeutic potential for obstructive renal injury (Manson et al., 2015a,b).

Tumor Necrosis Factor-α

TNF-α is a potent proinflammatory cytokine implicated in the pathophysiology of a wide range of renal disease (Donnahoo et al., 1999; Guo et al., 2001; Klahr and Morrissey, 1998). TNF-α is capable of upregulating its own expression as well as the expression of other inflammatory mediators (i.e., IL-1, nitric oxide, cell adhesion molecules, eicosanoids) and can recruit and stimulate various cells in the immune system. TNF-α is produced by resident renal tubular cells and infiltrating macrophage, and its expression is increased significantly in congenital and acquired renal obstruction (Chevalier et al., 2010; Kaneto et al., 1996; Misseri et al., 2005; Valles et al., 2003). TNF-α has a role in fibrotic renal injury, stimulating ECM accumulation and the upregulation of a number of cytokines and transcription factors involved in tubulointerstitial fibrosis, including TGF-β1. TNF-α is also a cytotoxic cytokine and has a significant role in obstruction-induced renal cell apoptosis (Misseri et al., 2005). Genetic deletion of the TNF-α receptor and inhibition of TNF-α pharmacologically cause a dramatic reduction in obstruction-induced renal fibrosis and apoptosis (Guo et al., 2001; Meldrum et al., 2007; Misseri et al., 2005), and inhibition of TNF-α has been shown to reduce tubulointerstitial fibrosis even when administered late in the course of renal injury (Khan et al., 2005).

Interleukin-18

IL-18 is a proinflammatory cytokine that has been found to be a sensitive and early marker of renal tubular damage; urinary IL-18 levels are predictive of acute tubular injury before creatinine levels and urine output become altered (Parikh et al., 2005). Liang et al. (2007) have also shown that circulating IL-18 levels and renal tubular IL-18 receptor expression is significantly increased in patients with chronic kidney disease. IL-18 expression is dramatically increased in response to obstruction and IL-18 has been shown to directly stimulate EMT in renal tubular cells in vitro and inflammatory cell infiltration and fibrotic injury in vivo via upregulation/activation of Toll-like receptor 4 (TLR4) (Meldrum et al., 2012). Inhibition of IL-18 activity prevents obstruction-induced EMT, fibroblast proliferation, and renal fibrosis independent of TGF-β1 and TNF-α activity, indicating that IL-18 is an important mediator of obstruction-induced renal injury through an alternative signaling mechanism (Bani-Hani et al., 2009).

Angiotensin II

The renin-angiotensin system has also been implicated in the pathophysiology of obstructive uropathy because of the substantial vasoconstriction of the renal vascular bed observed during renal obstruction. **Angiotensin II, a potent vasoconstrictor, is produced after conversion of angiotensin I to angiotensin II by the angiotensin-converting enzyme (ACE). Angiotensin II production is rapidly stimulated after onset of renal obstruction and has been linked to many of the pathophysiologic processes involved in obstruction, including altered hemodynamics and renal fibrosis** (Singh et al., 2016). Angiotensin II upregulates TGF-β1 and TNF-α expression during renal obstruction (Guo et al., 2001; Ishidoya et al., 1995), and ACE inhibition and inhibition of the angiotensin II receptor have been shown to decrease TGF-β1 expression, extracellular matrix deposition, macrophage recruitment, and the extent of obstruction-induced renal fibrosis (Guo et al., 2001; Klahr and Morrissey, 1997; Morrissey and Klahr, 1998). Angiotensin II has also been implicated in the perturbation of interstitial capillary circulation that occurs in fibrotic renal disease, resulting in chronic renal hypoxia and further stimulation of EMT and cytokine production (Norman et al., 2003; Zeisberg and Neilson, 2010). **Indeed, angiotensin II inhibition currently represents the principal clinical therapeutic approach to slowing or preventing the progression of most forms of renal disease** (Chevalier et al., 2009).

The biologic effects of angiotensin II are mediated through its interaction with one of two receptors: angiotensin II type I receptor (AT1) and angiotensin II type 2 receptor (AT2) (Bernstein and Berk, 1993). AT1 receptors, which mediate vasoconstriction and fibrosis, are more abundant and appear to be more biologically significant than AT2 receptors in adult mammalian kidneys (Meister et al., 1993; Sechi et al., 1992). Previous studies have demonstrated that AT1 receptor expression is increased in response to kidney obstruction (Yoo et al., 1998), and ACE inhibition and AT1 receptor blockade cause a significant reduction in obstruction-induced collagen expression, interstitial volume, and renal fibrosis (Guo et al., 2001; Klahr and Morrissey, 1997; Morrissey and Klahr, 1998). AT2 receptors predominate in fetal life, but AT2 receptor expression decreases in the first 3 to 14 days of life (Yoo et al., 1998). In the fetus, AT2 receptors have a vasodilating effect and appear to have a significant role in cellular proliferation and apoptosis (Chevalier et al., 1999a,b). Alterations in the developmental regulation of the renin angiotensin system appear to have a role in fetal obstruction as noted earlier (Ayan et al., 2001; Gobet et al., 1999).

Fibrosis and Extracellular Matrix in Obstructive Nephropathy

A universal characteristic of obstructive nephropathy appears to be renal fibrosis, although it is a nonspecific pattern seen in a variety of pathological conditions affecting the kidney (Eddy, 2000; Klein et al., 2011)**. It is seen as infiltration of the interstitium with abnormal amounts of extracellular matrix, including collagens, fibronectin, and other connective tissue proteins. Their presence disrupts the normal interconnections between cells that permit functional integration of the renal tissues.** Tubular cells may be disrupted and inadequately regulated. Cell:cell signaling by direct connection or paracrine messengers may be disrupted. Tissue oxygenation may be impaired. Fibrosis is a histopathological hallmark of many renal diseases.

The extracellular matrix is essential to normal function of the kidney as well, in terms of providing structural integrity and contributing to normal signaling systems. When abnormally expressed, however, it becomes detrimental (Chevalier, 2015; Klein et al., 2011). ECM homeostasis is a complex balance of synthesis and breakdown. Synthetic regulation is controlled by various mechanisms, including growth factors and signaling systems that are just being discerned. Mechanical forces contribute to these signals in various conditions, including hypertension and hydronephrosis. ECM breakdown is tightly regulated and represents the product of degradative enzymes, the matrix metalloproteinases (MMPs), and their endogenous inhibitors, the tissue inhibitors of metalloproteinases (TIMPs). This product is the proteolytic balance and is regulated by various cytokines, hormones, and mechanical forces. This balance has been studied vigorously in renal disease and to a limited degree in congenital obstruction (Ayan et al., 2001; Engelmyer et al., 1995; Gobet et al., 1999; Mure et al., 2006). In a neonatal murine model of partial obstruction, the degree of fibrosis and contralateral hypertrophy were not correlated with the degree of hydronephrosis in the affected kidney (Botto et al., 2011). The interaction of these systems is complex, and various compensatory pathways are likely to be present (Chevalier et al., 2009; Kim et al., 2001).

Modulation of renal fibrosis may be a significant potential target for managing obstructive nephropathy, but the delicate balance of these factors must be understood to a greater degree than at present (Eddy, 2005; Pap et al., 2017; Singh et al., 2016).

Mechanisms of Fibrosis

The most likely causes of excessive connective tissue include abnormal accumulation resulting from imbalance of synthesis and breakdown. It may also represent abnormal inductive signaling that produces excessive conversion of epithelium to mesenchymal tissue and connective tissues with this (Bascands and Schanstra, 2005; Burns et al., 2007; Zhang et al., 2007). These processes may be normal developmental sequences that persist because of the obstructive effect.

Cytokine Regulation.

Abnormal accumulation may represent simply excessive synthesis with no change in ECM breakdown. Increased collagen synthesis has been shown by upregulation of collagen gene expression in obstructive models (Fu et al., 2006; Liapis et al., 1994). Collagen synthesis is regulated in part by various cytokines, including TGF-β and the RAS. Reduced fibrosis may be seen when angiotensinogen activity is downregulated in an obstructed system (Fern et al., 1999; Kellner et al., 2006; Singh et al., 2016). Similar approaches have been demonstrated in nonobstructive fibrosis as well.

The role of TGF-β is complex and context dependent, yet inhibition of activity will produce less fibrosis as well (El Chaar et al., 2007; Isaka et al., 2000; Miyajima et al., 2000). There is evidence that TGF-β interacts and regulates the activity of the RAS, as well as regulating cellular growth dynamics. Fetal obstruction induces increased expression of TGF-β1 (Ayan et al., 2001; Medjebeur et al., 1997; Yang et al., 2001). Upregulation of the principle TGF-β receptors, TGF-βRI and TGF-βRII, have been demonstrated in fetal sheep ureteral obstruction (Yang et al., 2001). As reviewed earlier, TGF-β1 regulates EMT, thereby contributing to renal dysplasia (Yang et al., 2000). There is considerable interest in the role of TGF-β1 in promoting EMT of differentiated renal tubular epithelial cells in response to chronic ureteral obstruction. As shown in Fig. 40.5, renal interstitial fibroblasts, through transformation to myofibroblasts, play a pivotal role in the deposition of ECM in a hydronephrotic kidney. TGFβ-1 has also been shown to play a role in glomerular response to injury, because receptor inhibition protects glomerular integrity in the obstructed neonatal mouse model (Galarreta et al., 2013; Manson et al., 2014).

Epithelial-Mesenchymal Transition.

Although the role of fibroblasts in renal fibrosis is well accepted, their origin and process of activation remains controversial. Resident interstitial fibroblasts, bone marrow fibroblasts, migrating leukocytes, and vascular endothelial cells are potential sources of renal interstitial fibroblasts. **Growing evidence suggests that under pathological conditions renal tubular epithelial cells can also undergo a phenotypic transformation into matrix-producing myofibroblasts by EMT** (Bani-Hani et al., 2009; Baum et al., 2008; Healy and Brady, 1998; Strutz et al., 1995). These activated fibroblasts acquire mesenchymal markers, migrate into the interstitial space across damaged tubular basement membranes, and become capable of producing extracellular matrix (Liu, 2010). EMT appears to be a major contributing factor to tubulointerstitial fibrosis in the obstructed kidney, and Iwano et al. (2002) have demonstrated that a substantial number of interstitial fibroblasts originate from tubular epithelium during renal obstruction. In fact, selective blockade of EMT in animal models impressively reduces fibrosis after obstructive injury, underscoring the importance of EMT in renal fibrogenesis (Iwano et al., 2002; Yang and Liu, 2002). More recent studies using a cell lineage-tracing technique demonstrate that a substantial number of interstitial fibroblasts are also derived from capillary endothelial cells (Zeisberg et al., 2008). The extent to which EMT contributes to renal fibrosis in human chronic kidney disease is a matter of debate, because it is impossible to use cell lineage-tracing techniques. Although a loss of epithelial markers (i.e.. E-cadherin, zonula occludens-1 [ZO-1]) and an increase in mesenchymal markers (i.e., α-SMA, fibroblast specific protein-1 [FSP-1], vimentin) suggest the existence of EMT in adult and fetal models of kidney obstruction (Lange-Sperandio et al., 2007; Liu, 2010; Mure et al., 2006; Murer et al., 2006), these markers are not absolutely specific for EMT. The early inflammatory phase of renal fibrosis plays a decisive role in initiating EMT (Liu, 2010), as a number of growth factors and cytokines released during this phase regulate EMT, of which TGF-β1 is the chief and most studied mediator. In addition to TGF-β, TNF-α, IL-18, angiotensin II, FGF-2, MMP-2, and MMP-9 have been implicated in renal tubular cell EMT (Bani-Hani et al., 2009; Liu, 2010).

Many of the steps involved in the transformation of tubular epithelial cells are regulated by TGF-β1; these steps include loss of cell adhesion, expression of α-

SMA, disruption of tubular basement membrane, and cell migration to the interstitium (Liu, 2004). Signaling by TGF-β1 is mediated in part by Smads, which are profibrotic (Smad2 and Smad3) and inhibitory (Smad7). Thus targeted deletion of Smad3 reduces apoptosis and fibrosis in mice with ureteral obstruction, whereas gene therapy with Smad7 also reduces fibrosis (Lan et al., 2003; Sato et al., 2003). TGFβ-1 also acts through downregulation of transcriptional co-repressors of the Smads, SnoN and Ski (Yang et al., 2003). In contrast, hepatocyte growth factor (HGF) blocks EMT by blocking Smad2 and Smad3, and gene therapy with HGF reduces fibrosis in rats with ureteral obstruction (Gao et al., 2002; Yang and Liu, 2003). HGF also acts by upregulating the Smad co-repressors SnoN and Ski, countering the action of TGFβ-1 (Yang et al., 2005).

These complex networks of counterbalancing factors provide many potential opportunities for therapeutic intervention to prevent the progression—or even promote the reversal—of interstitial fibrosis resulting from obstructive nephropathy (Fogo, 2003). EMT, as a gene directed process, is uniquely suited to pharmacologic manipulation and may therefore have therapeutic potential in the management of patients with fibrotic renal disease.

Dysregulation of the Proteolytic Balance.

Fibroblasts in the renal interstitium are considered the primary source of extracellular matrix, and tubulointerstitial fibrosis is associated with a significant accumulation of matrix-producing fibroblasts. In response to stimulation from cytokines and growth factors, fibroblasts will secrete collagen, elastin, proteoglycans, and fibronectin into the interstitial space (see Fig. 40.2). This process is normally tightly regulated by MMPs, a family of enzymes responsible for tissue remodeling and the degradation of collagenous and noncollagenous components of extracellular matrix. MMPs are excreted by a variety of cells, including fibroblasts, endothelial cells, macrophage, and lymphocytes, in an inactive form that requires further processing to become active. Control of MMP activity occurs in the activation of the latent enzyme and with direct inhibition of the active enzyme (Ronco et al., 2007). TIMPs are produced by tubular cells and interstitial cells in the kidney, and they function to inhibit the activity of MMPs. Dramatic increases in TIMP expression have been demonstrated in response to obstruction (Engelmyer et al., 1995; Kim et al., 2001). It has been postulated that increased extracellular matrix deposition during obstructive injury is due to increased TIMP inhibition of MMPs.

The role of MMPs in renal fibrosis, however, appears to be much more complex than originally theorized. MMP-2 and MMP-9 have been the focus of most studies in the kidney. Although some studies demonstrate an acceleration of renal fibrosis with pharmacologic inhibition of MMP-2 and MMP-9 (Zeisberg et al., 2006), more recent studies in knockout mice suggest that MMP-9 is an important mediator of obstruction-induced renal fibrosis and EMT independent of TGF-β expression (Wang et al., 2010). MMP-9 has been demonstrated to promote EMT by stimulating E-cadherin shedding and tubular basement membrane degradation, and it can also release and activate a variety of profibrotic growth factors and cytokines sequestered in the ECM upon proteolysis (Matsui et al., 2017). Mice overexpressing MMP-2 similarly exhibit interstitial fibrosis, glomerulosclerosis, tubular atrophy, and renal failure in the absence of superimposed injury (Cheng et al., 2006). In addition to their degradative effect on extracellular matrix, it appears that MMPs can disrupt tubular basement membrane integrity, release cytokines and growth factors sequestered in the ECM, and trigger epithelial-to-mesenchymal transition, all processes that contribute to the development of renal fibrosis.

Altered activity and regulation of the MMPs and TIMPs have been studied in the kidney (Eddy, 1996) in several conditions. It is clear that they are important regulators of the state of the ECM. Their expression has been shown in the developing kidney as well and in postnatal obstruction, they are altered in activity. In prenatal obstruction increased expression (Ayan et al., 2001; Mure et al., 2006), and activity (Gobet et al., 1999) has been shown as well as in congenital reflux-related fibrosis (Gobet et al., 1998). The precise regulators of the MMPs and TIMPs in development and obstruction are not well defined but are likely to be an important element in the development of pathological fibrosis (Pap et al., 2017) and may involve mechano-cellular signaling pathways (Park et al., 1999). There is some evidence of regulation by the RAS and TGF-β as well, which opens therapeutic options for the treatment of fibrosis (Bolbrinker et al., 2006; Diamond et al., 1998; Ding et al., 2005; Yang et al., 2007).

Other Mechanisms.

Oxidative stress in the developing kidney is a probable contributor to fibrotic and inflammatory pathways in obstructive uropathy. The ability of the immature kidney to mount an appropriate response to increased oxidative stress may define the degree of functional and developmental impairment suffered (Chevalier et al., 2014; Manucha and Valles, 2008; Rinaldi et al., 2010).

Hypoxia may be a factor in the development of tissue fibrosis as well in response to induction of hypoxia-inducible factors-1 and 2 (HIF-1 and HIF-2) (Higgins et al., 2008). In vitro stimulation of renal epithelia with HIF-1 increases EMT, known to induce fibrosis. Genetic models that do not express HIF-1α develop less fibrosis and inflammatory infiltration in response to ureteral obstruction in postnatal models (Higgins et al., 2007). The role in prenatal obstruction remains undefined but potentially relevant.

Nitric oxide (NO) has also been shown to regulate the development of obstructive fibrosis in postnatal animals and may play a similar role prenatally (Felsen et al., 2003; Huang et al., 2000; Manucha and Valles, 2008; Yoo et al., 2010). Increased NO generation reduces the degree of interstitial fibrosis (Ito et al., 2004), and in animals without the gene to produce NO synthase, unilateral ureteral obstruction (UUO) produces a greater degree of fibrosis than in those animals with this enzyme intact (Hochberg et al., 2000). Data suggest a greater potential role for nitric oxide derived from endothelial nitric oxide synthase (eNOS) than inducible nitric oxide synthase (iNOS) (Chang et al., 2002; Huang et al., 2000).

Fibrosis is clearly a major component of the pathophysiology of congenital obstruction. Understanding the role and activities of the various components of this system may permit more specific diagnosis through urinary biomarkers reflecting the elements of the system. These elements may also be relevant targets of therapeutic intervention to modulate ECM homeostasis.

Apoptosis.

Apoptosis, or programmed cell death, is the major mechanism by which renal tubular cell death and a reduction in renal mass occur after renal obstruction (Gobe and Axelsen, 1987; Manucha and Valles, 2012; Nilsson et al., 2015; Truong et al., 1998). Apoptosis is present in normal and disease states and can be triggered by either a death receptor signaling pathway (i.e., TNF-α binding to its receptor) or an intrinsic pathway involving disturbances in the mitochondrial membrane and release of cytochrome c. After stimulation of either of these signaling pathways, caspases (cysteinyl aspartate-specific proteinases) become activated, which are a family of 12 enzymes that act as the effector molecules for apoptosis. Caspases cleave various nuclear and cytoplasmic substrates, resulting in nuclear fragmentation and condensation. The cell is then broken down into multiple membrane-bound spheric bodies, called apoptotic bodies, which are phagocytized by adjacent healthy cells. As compared with necrosis, this unique mechanism of cell death maintains cell membrane integrity and thereby minimizes the involvement of inflammatory scavenger cells and the overall inflammatory response (Wyllie et al., 1980). **Renal tubular and interstitial cells are most susceptible to apoptotic cell death during renal obstruction in mature kidneys** (Truong et al., 1998). Choi et al. (2000) demonstrated renal tubular cell apoptosis beginning after 4 days and peaking after 15 days of renal obstruction, whereas interstitial cell apoptosis increased progressively over the duration of renal obstruction. Glomerular cells, on the other hand, appear to be very resistant to obstruction-induced apoptosis, with no evidence of glomerular cell apoptosis occurring after 90 days of renal obstruction (Truong et al., 1998). **In the neonatal kidney, glomerular and tubular cells are susceptible to apoptotic cell death, with progressive apoptosis resulting in a decrease in the number of glomeruli, tubular atrophy, and glomerulotubular disconnection, ultimately resulting in the development of nonfunctioning nephrons** (Cachat et al., 2003; Klein et al., 2011; Thornhill et al., 2005).

Many of the cytokines and vasoactive factors implicated in EMT and tubulointerstitial fibrosis also appear to mediate apoptotic cell death in response to renal obstruction, in part by increasing caspase expression and activation. TGF-β1 directly stimulates renal tubular cell apoptosis in vitro (Schuster and Krieglstein, 2002; Yang et al., 2006), and TGF-β1 inhibition has been shown to prevent obstruction-induced and stretch-induced renal tubular cell apoptosis (Miyajima et al., 2000, 2001). TNF-α is a directly cytotoxic cytokine that induces apoptosis in many cells, including renal tubular cells, through interactions with its membrane-bound receptors, TNFR1 and Fas. The expression of TNF-related apoptotic molecules (e.g., TNFR1 and Fas) increase in parallel to observed increases in obstruction-induced tubular cell apoptosis (Choi et al., 2000). TNF-α neutralization has been shown to ameliorate obstruction-induced apoptosis and pro-apoptotic signaling (Misseri et al., 2005). IL-18 has similarly been demonstrated to be an important mediator of renal tubular cell apoptosis in vitro and in response to UUO (Zhang et al., 2011). The effect of angiotensin II on obstruction-induced apoptosis is less clear. Morrissey and Klahr (1999) demonstrated that an angiotensin II type 2 receptor antagonist inhibits obstruction-induced apoptosis, but other investigators have found no benefit of either ACE inhibitors or angiotensin II type 2 receptor antagonists in preventing obstruction-induced apoptosis in the mature kidney (Chevalier et al., 1999a,b; Radovic et al., 2008). These diverging cellular responses to a single stimulus suggest that renal tubular epithelial cells may undergo an adaptive (EMT) vs. death response (apoptosis) depending on the degree or duration of stimulation.

Emerging Therapeutic Options

Although it has been demonstrated that inhibition of profibrotic cytokines and growth factors can prevent obstruction-induced renal injury, these treatment options often do not translate well into clinical medicine because therapy is nontargeted and can result in unwanted systemic effects on the immune system and other nonpathological organ systems. Stem cell therapy has recently emerged as an exciting alternative therapy. Mesenchymal stem cells (MSCs) have the capacity to home or migrate specifically to injured tissue and produce an array of cytokines and growth factors that act in a paracrine fashion to repair damaged tissue and limit inflammatory injury (Sohni and Verfaillie, 2013). Although mesenchymal stem cell (MSC)-based therapies have been shown to confer renal protection in several clinical trials and animal models of acute kidney injury (AKI) (Herrera et al., 2004; Kim et al., 2012; Tan et al., 2012; Westenfelder and Togel, 2011), the potential of MSC-based therapy to ameliorate chronic kidney disease is only beginning to be elucidated. Exogenous administration of MSCs has been demonstrated to reduce renal tubulointerstitial fibrosis, collagen deposition, and EMT in response to chronic obstructive renal injury (Asanuma et al., 2011; Bai et al., 2013), and MSCs conditioned medium has been shown to rescue kidney function and significantly reduce tubulointerstitial fibrosis and tubular atrophy in animals with established CKD (van Koppen et al., 2012). MSCs secrete BMP7 in vitro, and MSCs have been shown to ameliorate diabetic glomerulosclerosis in vivo and in vitro by inhibiting TGF-β signaling via secretion of BMP7 (Lv et al., 2014). Interestingly, although MSCs are undetectable in the kidney 2 weeks after injection, they appear to confer renal protection and decrease renal fibrosis for up to 3 months after delivery (Semedo et al., 2009). A greater understanding of the mechanisms of MSC-induced renoprotection may facilitate the development of new therapeutic options for patients with irreversible obstruction-induced renal damage.

Key Points: Mechanisms of Obstructive Uropathy

- Chronic ureteral obstruction leads to renal inflammation, increased extracellular matrix formation, tubulointerstitial fibrosis, and apoptosis, thus limiting the potential for return of renal function.
- Inflammatory infiltration is not a prominent characteristic of fetal kidney obstruction, suggesting a fundamentally distinct mechanism for the pathophysiology of congenital obstruction as compared with postnatally acquired kidney obstruction.
- TGF-β1 is a major regulator of renal fibrosis via stimulation of epithelial-to-mesenchymal transition, fibroblast proliferation, extracellular matrix synthesis, and the simultaneous inhibition of collagenase and degradative matrix metalloproteinases.
- BMP7 is a member of the TGF-β superfamily that is activated after correction of renal obstruction and promotes the resolution of fibrosis and the restoration of normal renal architecture.
- Angiotensin II production is rapidly stimulated after the onset of renal obstruction and has been linked to many of the pathophysiologic processes involved in obstruction, including altered hemodynamics, inflammatory infiltration, and renal fibrosis.
- Fibroblasts in the renal interstitium are considered the primary source of extracellular matrix, and tubulointerstitial fibrosis is associated with a significant accumulation of matrix-producing fibroblasts.
- Evidence suggests that under pathological conditions, renal tubular epithelial cells can undergo a phenotypic transformation into matrix-producing myofibroblasts by a process called epithelial-to-mesenchymal transition. These activated fibroblasts acquire mesenchymal markers, migrate into the interstitial space across damaged tubular basement membranes, and become capable of producing extracellular matrix.
- Renal tubular cells are most susceptible to apoptotic cell death during renal obstruction in mature kidneys, whereas glomerular and tubular cells are susceptible to apoptotic cell death in neonatal kidneys.

Hemodyamic Changes With Obstruction

Glomerular Filtration and Renal Blood Flow

There are many functional changes in the kidney associated with obstructive nephropathy that affect renal hemodynamics. To understand the relationship between changes in renal hemodynamics and the alterations in glomerular filtration rate (GFR) that occur during and after obstruction, it is important to understand all of the factors that influence GFR. GFR is defined by the equation

$$\mathrm{GFR} = K_f(P_{GC} - P_T - \pi_{GC})$$

where K_f is a glomerular ultrafiltration coefficient related to the surface area and permeability of the capillary membrane. P_{GC} refers to glomerular capillary pressure, which is influenced by renal plasma flow and the resistances of the afferent and efferent arterioles. The hydraulic pressure driving fluid into Bowman space is resisted by the hydraulic pressure of fluid within the renal tubules (P_T) and $\pi_{GC,}$ which is the oncotic pressure of proteins in the glomerular capillary and efferent arteriole. In addition to tubular hydraulic pressure and the oncotic pressure of proteins in the capillary, glomerular capillary pressure is also influenced by renal plasma flow (RPF): R_{aff}

$$\mathrm{RPF} = (\text{Aortic pressure} - \text{Renal venous pressure})$$

Renal Vascular Resistance

Renal vascular resistance is primarily mediated by changes in the resistance of the afferent and efferent arterioles; therefore constriction of the afferent arteriole will result in a decrease in P_{GC} and GFR, whereas constriction of the efferent arteriole will increase P_{GC}. Renal obstruction can transiently or permanently affect some or all of the determinants of GFR depending on the length and degree of obstruction.

Unilateral Ureteral Obstruction

There are differences in the hemodynamic changes that occur in response to UUO as compared with bilateral ureteral obstruction (BUO). **Animal experiments have demonstrated a triphasic pattern of renal blood flow (RBF) and ureteral pressure changes during UUO (Fig. 40.7).** Initially, there is an increase in pressure within the renal tubules of the affected kidney secondary to obstruction and a subsequent decrease in GFR. **The vasculature of the kidney attempts to compensate for the decreased GFR with an increase in renal blood flow mediated by the release of vasodilators, such as prostaglandin E_2 (PGE_2)** (Allen et al., 1978) **and NO** (Lanzone et al., 1995). This phase lasts 1 to 2 hours. During the second phase, lasting 3 to 4 hours, ureteral pressure remains elevated, but renal blood flow begins to decline, and in the final phase, ureteral pressure and renal blood flow progressively decline, resulting in a gradual loss in renal function (Moody et al., 1975; Vaughan et al., 1970). The late phase decline in RBF and ureteral pressure appears to be mediated by an increase in afferent arteriolar resistance. In addition to impeding RBF, increased afferent arteriolar resistance causes a decrease in effective glomerular capillary pressure and a resulting decrease in renal tubular pressure (Arendshorst et al., 1974). During the late phase of obstruction, there is also a shift in RBF from the outer cortex to the juxtamedullary region of the kidney and large portions of the cortical vascular bed become unperfused or underperfused (Yarger and Griffith, 1974). **Reduced GFR at this stage is therefore not only the result of a reduction in P_{GC} in individual glomeruli because of increased afferent arteriolar resistance but also the result of a global lack of perfusion of many glomeruli.**

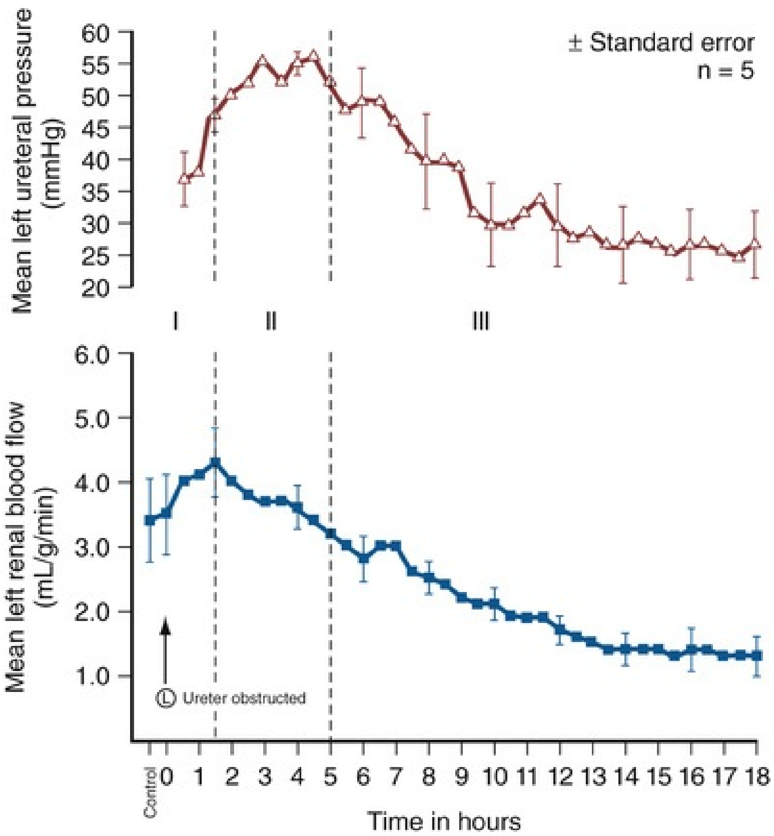

FIG. 40.7 Triphasic relationship between ipsilateral renal blood flow and left ureteral pressure during 18 hours of left ureteral obstruction. The three phases are designated by Roman numerals and separated by *vertical dashed lines*. In phase I, renal blood flow and ureteral pressure rise together. In phase II, the renal blood flow begins to decline and ureteral pressure remains elevated. In phase III, the blood flow and ureteral pressure decline together. (From Moody TE, Vaughan ED JR, Gillenwater JY: Relationship between renal blood flow and ureteral pressure during 18 hours of total ureteral occlusion. Implications for changing sites of increased renal resistance. *Inves Urol* 13:246–251, 1975.)

The mechanism of obstruction-induced increased afferent arteriolar resistance was initially thought to be due to upregulation of the renin-angiotensin system or increased thromboxane A_2 expression, but subsequent studies have not revealed a significant effect of these mediators on the renal hemodynamic response to obstruction (Vaughan et al., 2004). More recently, NO has been implicated in the late renal hemodynamic changes observed during UUO. NO is a vasodilator formed by the conversion of arginine to NO by nitric oxide synthase (NOS). NOS is present in the kidney and iNOS is upregulated in the kidney in response to obstruction (Miyajima et al., 2001). A study by Felsen et al. demonstrated that animals administered L-arginine demonstrated an increase in RBF and ureteral pressure in response to obstruction that was not observed in controls, suggesting that a lack of availability of substrate for NO production may be the mechanism of late phase decreases in RBF and tubular pressure (Felsen et al., 2003).

Bilateral Ureteral Obstruction or Obstruction of a Solitary Kidney

BUO (or obstruction of a solitary kidney) is characterized by only a modest initial increase in renal blood flow lasting about 90 minutes, followed by a decrease in bilateral renal blood flow (Gulmi et al., 1995)**. Unlike UUO, in which the ureteral pressure is initially elevated but quickly decreases to preocclusion pressures by 24 hours, ureteral pressure remains elevated for at least 24 hours with BUO. This prolonged elevation in intratubular pressure contributes to the decrease in GFR observed with BUO.** It has been shown, however, that the decrease in GFR and RBF is more pronounced in animals with UUO compared with BUO (Siegel et al., 1977). The mechanism of these hemodynamic differences appears to be related to the site of vasoconstriction in the glomerulus. During UUO, preglomerular vasodilation is followed by a more prolonged preglomerular vasoconstriction, and this increase in afferent arteriolar resistance causes a reduction in glomerular capillary pressure that, in turn, results in decreased intratubular pressure. **In contrast, during BUO, preglomerular vasodilation is followed by a prolonged postglomerular vasoconstriction. This increase in efferent arteriolar resistance results in increased P_{GC} and intratubular pressure despite a decrease RBF. The positive effect of increased P_{GC} on GFR is offset by the persistent elevation in tubular pressure.** As with UUO, it appears that nitric oxide has an important role in early vasodilation of the afferent arteriole (Reyes and Klahr, 1992). A number of other vasoactive mediators have been implicated in the hemodynamic changes observed during BUO. Inhibition of platelet-activating factor (PAF), a potent vasodilator, has been shown to significantly decrease GFR and effective renal plasma flow (ERPF) in animals with BUO (Reyes and Klahr, 1991), whereas inhibition of endothelin (a vasoconstrictor) in animals with BUO has been shown to attenuate the observed decreases in GFR and ERPF (Reyes and Klahr, 1992). Although a number of different vasoactive mediators likely contribute to the hemodynamic response during BUO, **atrial natriuretic peptide (ANP) appears to have a unique role in BUO and may be largely responsible for the different hemodynamic response observed with**

BUO as compared with UUO. Because there is no second renal unit to compensate for the ureteral obstruction, intravascular volume increases in response to BUO and serves as a stimulus for secretion of ANP. ANP, in turn, increases afferent arteriolar dilation and efferent arteriolar vasoconstriction, leading to an increase in P_{GC} and intratubular pressure (Maack, 1996). It also decreases the sensitivity of tubuloglomerular feedback, inhibits release of renin, and increases the glomerular ultrafiltration coefficient, K_f, which is related to the surface area and permeability of the capillary membrane. Indeed, high plasma levels of ANP have been demonstrated in animals with BUO as compared with control animals or those with UUO (Kim et al., 2001; Purkerson et al., 1989), and it has been postulated that increased levels of ANP may exert a protective effect on GFR during BUO that is not seen with UUO.

The intrarenal distribution of blood flow is also different with BUO as compared with UUO. **Animal studies have demonstrated that there is shift of blood flow from the juxtamedullary region of the kidney to the outer cortex in response to BUO, which is the opposite of that seen with UUO** (Jaenike, 1972; Solez et al., 1976). These alterations in the distribution of renal cortical blood flow may also contribute to the differences in GFR observed between BUO and UUO.

In summary, the hemodynamic changes observed with UUO and BUO involve increases in renal vascular resistance and ureteral pressure. The timing and regulation of these changes; however, are different (Fig. 40.8). During UUO, early renal vasodilation is followed by prolonged preglomerular vasoconstriction that results in normalization of intratubular pressure. In contrast, during BUO there is little early vasodilation and the later postglomerular vasoconstriction is associated with increased intratubular pressures.

Partial Ureteral Obstruction

Although most models of urinary tract obstruction study complete obstruction over variable periods of time, many clinical situations involve partial ureteral obstruction (PUO). The effect of PUO on renal hemodynamics and GFR are variable depending on the severity and the duration of obstruction. In general, PUO results in decreased renal blood flow and GFR in the ipsilateral kidney (Wen, 2002; Wen et al., 1999). Chronic PUO has been reported to decrease RBF to 25% of normal (Stecker and Gillenwater, 1971), and a shift in renal cortical blood flow from the outer cortex to the inner cortex has been documented. It appears that the degree of RBF decline is dependent on the severity of obstruction (Chevalier, 1984; Chevalier and Kaiser, 1984). Although PUO has not been studied as extensively as complete UUO, a similar array of vascular mediators have been implicated in the increased afferent arteriolar resistance that occurs in response to PUO, including prostaglandins (Ichikawa and Brenner,

1979) and the renin-angiotensin system (Beharrie et al., 2004). A major problem with studies involving partial obstruction is the ability to accurately reproduce the degree of obstruction in each animal. Thornhill et al. (2005) describe a method of a ligating the ureter over a wire of calibrated diameter, which can then be removed to create a partial obstruction. The authors found that when the ureter was reduced by 70% to 75% that GFR was reduced by 80% after 28 days of partial UUO.

Key Points: Hemodynamic Changes With Obstruction

- With unilateral ureteral obstruction, renal blood flow increases during the first 1 to 2 hours. It begins to decrease at 3 to 4 hours and markedly declines after 5 hours of obstruction.
- The increase in renal blood flow in UUO is a result of relaxation of afferent arterials in which PGE_2 and NO play a role.
- Reduction in whole-kidney GFR after prolonged obstruction is due to afferent arteriolar vasoconstriction mediated by the renin-angiotensin system.
- In BUO, there is a modest increase in renal blood flow lasting approximately 2 hours, followed by a profound decline in renal blood flow.
- In UUO there is a shift of blood flow from the outer cortex to inner cortex. In bilateral ureteral obstruction, the shift is in the opposite direction toward the outer cortex.

Effects of Obstruction on Tubular Function

Obstruction of one or both kidneys can have profound effects on the concentrating ability of the kidney and on sodium, potassium, and hydrogen excretion. The ability of the kidney to recover normal excretory function after relief of obstruction is dependent on the degree and severity of obstruction. **A postobstructive diuresis often accompanies relief of bilateral ureteral obstruction but is not typically observed with relief of UUO, secondary to the presence of a functional contralateral kidney that can maintain fluid balance.** The eventual correction of abnormal renal tubular function depends on the degree and duration of obstruction.

Urinary Concentrating Ability

Normal urine concentrating ability is dependent on a hypertonic medullary interstitial gradient, which is established by active sodium transport out of the tubule and the countercurrent exchange mechanism. It is also dependent on the variable permeability of the tubules to water, mediated by aquaporin water channels. Obstructive nephropathy can disrupt all or some of these mechanisms and lead to a defect in urine concentrating ability.

Aquaporins (AQPs) are protein channels that form pores in the membrane of renal tubular cells. AQPs selectively conduct water into and out of the cell and are essential for the urine concentrating ability of the kidney. **Aquaporin 2 (AQP2) is exclusively expressed in the principal cells of the collecting tubule and collecting duct and is the predominant vasopressin-regulated water channel.** Vasopressin is secreted into the bloodstream from the posterior pituitary gland in response to increased serum osmolality or a reduction in circulating volume. After vasopressin binding to cell surface receptors in the collecting tubule, cytoplasmic vesicles containing AQP2 channels fuse with the apical membrane of tubular cells to facilitate water movement out of the collecting duct and its subsequent reabsorption.

After 24 hours of bilateral ureteral obstruction there is a marked reduction in AQP2 expression in the kidney (Frokiaer et al., 1996; Stodkilde et al., 2011), which results in an impaired ability of the kidney to reabsorb water once the obstruction has been relieved. It has been demonstrated that AQP2 expression remains 50% of normal levels 7 days after relief of obstruction. AQP1, AQP3, and AQP4 expression levels have also been shown to be downregulated in response to BUO (Li et al., 2001), and although AQP2 and AQP3 expression normalize within 30 days of release of BUO, **AQP1 remains downregulated and may contribute to the long-term polyuria and impaired concentrating ability of obstructive nephropathy.** Downregulation of AQP channels are also observed in response to UUO, but the clinical manifestations are not as evident because the contralateral kidney is able regulate fluid balance. A significant decrease in AQP2 levels are observed in the obstructed kidney (23% normal) and a moderate decrease in AQP2 levels are observed in the nonobstructed kidney (75% normal) after 24 hours of UUO (Frokiaer et al., 1997), suggesting a local and a systemic effect on AQP expression. Angiotensin has been implicated in obstruction-induced AQP2 downregulation, because blockade of the angiotensin I receptor has been shown to prevent the decreased expression of AQP2 (Jensen et al., 2006), and antioxidants, such as N-acetylcysteine, appear to upregulate AQP2 expression and protect against the urinary concentrating defect caused by obstructive injury (Shimizu et al., 2008). Neonatal complete or partial UUO similarly induces a reduction in the expression and distribution of aquaporins (AQP1, AQP2, AQP3, AQP7) (Klein et al., 2011), and AQP1 through AQP4 expression has been shown to be reduced in pediatric patients with congenital hydronephrosis in proportion to the degree of renal functional impairment detected on DTPA renal dynamic imaging (Li et al., 2012).

Sodium Transport

A decrease in sodium transport in the nephron is observed after release of obstruction, and this salt wasting also contributes to the concentrating defect observed in response to obstruction. Previous studies have indicated that the major defects in renal tubular sodium reabsorption localize to the distal segments of the nephron (Jensen et al., 2006; Li et al., 2003). A significant downregulation in major sodium transporters occurs within the nephron 24 hours after the onset of UUO and occurs in the obstructed and unobstructed kidneys. Similarly, a significant downregulation in major sodium transporters occurs in response to BUO, and in both models of injury, the downregulation in sodium transporters has been shown to contribute to the observed natriuresis (Jensen et al., 2006; Li et al., 2003). A significant reduction in the expression and distribution of major sodium transporters has also been demonstrated in neonatal kidneys in response to complete and partial UUO (Klein et al., 2011). **The natriuresis after relief of BUO is typically greater than that after UUO because BUO causes retention of sodium, water, urea nitrogen, and increased production of ANP, all of which stimulate sodium wasting after relief of obstruction.**

Prostaglandin E_2 has an important role in tubular water and salt transport and the regulation of renal hemodynamics (Harris and Breyer, 2001). It has been demonstrated that PGE_2 inhibits NaCl reabsorption in the thick ascending limb of the loop of Henle and vasopressin-induced increases in water permeability in collecting ducts (Aarab et al., 1999; Torikai and Kurokawa, 1983). Cyclooxygenase (COX) is the rate-limiting enzyme in the synthesis of prostaglandin from arachidonic acid, and Norregaard et al. (2005) have demonstrated that COX-2 and PGE_2 synthesis are upregulated in the kidney in response to 24 hours of BUO and that COX-2 inhibition prevents PGE_2 release and the observed downregulation in AQP2 and major sodium channel expression in response to obstruction.

Hydrogen Ion Transport and Urinary Acidification

Obstruction causes a deficit in urinary acidification that has been demonstrated in human subjects as well as animal models. The defect is characterized by the inability of the kidney to lower urinary pH maximally (<5.5) under the stimulus of systemic acidemia. Evidence suggests that the major acidification defect is in the distal nephron, most likely related to defective H+ secretion in the distal tubule and collecting duct, and/or decreased bicarbonate reabsorption in the juxtamedullary nephron. Obstruction has been demonstrated to significantly decrease the expression of multiple acid-base transporters in the kidney, including the type 3 Na^+/H^+ exchanger, the electrogenic Na^+/HCO_3^- cotransporter, the Na^+-K^+ (NH_4^+)-$2Cl^-$ cotransporter, and the electroneutral Na^+/HCO_3^- cotransporter, in addition to decreasing the expression of H^+-ATPase in the kidney (Wang et al., 2009). Valles et al. (2000) demonstrated that the decrease in H^+-ATPase observed during UUO is mediated by an increase in iNOS, which in turn, appears to be regulated by angiotensin II. Neonatal kidney obstruction similarly results in a downregulation of acid-base transporters, resulting in decreased acid secretion and the development of metabolic acidosis in a time- and age-dependent fashion (Wang et al., 2009).

In the proximal tubule, glutamine uptake and ammonia generation are diminished after release of obstruction, resulting in a greater proportion of H^+ that will be buffered as a titratable acid in combination with phosphate, creatinine, and other bases. The largest component of titratable acid is phosphate, and because phosphate excretion may be compromised in response to obstruction, the net result may be a lower urinary pH related to unbuffered protons in spite of a net decrease in total H^+ secretion.

Other Cation Transport

Obstruction has an effect on other cation transport as well. In UUO potassium secretion is decreased in proportion to the decrease in GFR after release of a 24-hour period of UUO (Harris and Yarger, 1975). This may be due to reduced delivery of sodium to the distal nephron and a low-flow state, although other investigations indicate an intrinsic defect in potassium secretion as well (Thirakomen et al., 1976). In contrast, potassium excretion increases in parallel with sodium excretion after relief of BUO, and it appears that proximal reabsorption of potassium remains unchanged, whereas its secretion in the collecting duct is increased after relief of obstruction. This may be related to increased water and sodium delivery to the collecting duct and to the presence of high levels of ANP that can stimulate potassium secretion in the distal nephron (Sonnenberg and Wilson, 1976). Magnesium excretion is also markedly increased after release of either UUO or BUO. This most likely results from compromised transport in the thick limb of Henle. The effects on phosphate reabsorption after the release of obstruction vary depending upon whether it was bilateral or unilateral. When BUO is released, accumulated phosphate is rapidly excreted in proportion to sodium (Beck, 1979). Conversely, a decrease in phosphate excretion and a net retention occur with release of UUO.

Egress of Urine From the Obstructed Kidney

Although normal flow of urine from the kidney through the urinary tract is compromised with obstruction, urine may still egress from the kidney. A rupture of the calyceal fornix and subsequent extravasation of urine can occur during acute obstruction, typically in response to ureteral stones (Stenberg et al., 1988), although it can also be seen with congenital abnormalities such as posterior urethral valves. Extravasation of urine into the venous and lymphatic system may also occur in the setting of urinary obstruction. During chronic obstruction, fluid is thought to exit primarily into the renal venous system.

Clinical Impact of Renal Obstruction

Hypertension

Hypertension can develop in response to urinary tract obstruction and is more common in the presence of BUO as compared with UUO. Vaughan and Gillenwater (1973) noted hypertension in 17 of 22 patients with BUO that was reversible upon relief of obstruction in all but 2 patients. Increased ANP levels and intravascular volume have been documented in patients with BUO and suggest a volume-mediated mechanism for hypertension in these patients. Hypertension is less common in patients with UUO and does not appear to be related to volume overload because the normal contralateral kidney is able to eliminate excess volume and solutes (Al-Mashhadi et al., 2015). The renin-angiotensin system is upregulated in response to UUO and has been implicated as the mechanism of hypertension in these patients. Previous studies have demonstrated that blockade of the angiotensin II type 2 receptor with losartan prevents the rise in systolic blood pressure associated UUO and normalizes systolic blood pressure in chronically hypertensive UUO rats (el-Dahr et al., 1993). **Hypertension is therefore more likely to occur in response to BUO and more likely to be reversed after relief of obstruction in patients with BUO as compared with UUO** (Al-Mashhadi et al., 2015, 2018).

Compensatory Renal Growth

First described by Hinman in 1943, compensatory renal growth refers to the development of increased volume of the contralateral kidney in response to unilateral ureteral obstruction or renal agenesis (Peters et al., 1993; Taki et al., 1983). **The development of contralateral renal growth is influenced by age and the degree and duration of obstruction.** Studies in human subjects subjected to nephrectomy have demonstrated that a reduction in renal compensatory growth occurs with increasing age (Edgren et al., 1976). Compensatory renal growth appears to be directly proportional to the duration of obstruction and is less prominent with partial rather than complete UUO (Chevalier and Kaiser, 1984; Chevalier et al., 1987, 1999a-d; Eskild-Jensen et al., 2001). Interestingly, a recent study also demonstrated that compensatory renal growth, renal hypertrophy, and GFR are increased in response to unilateral nephrectomy in male rats as compared with female rats or gonadectomized groups (Azurmendi et al., 2013), suggesting that sex hormones have a role in this adaptive response as well. **Although the kidney enlarges, an increase in the number of nephrons or glomeruli does not occur in utero, indicating that the increase in renal volume is primarily a consequence of cellular hypertrophy rather than hyperplasia** (Peters et al., 1993). A study in fetal sheep, however, demonstrated that animals subjected to 5/6 nephrectomy had increased cortical thickness, tubular hypertrophy, a lower glomerular density, but a striking increase in glomerular number as compared with animals subjected to 1/2 nephrectomy. Furthermore, the magnitude of the regenerative process appeared to be more dependent on the severity of renal reduction than on the timing of renal reduction (Sammut et al., 2013). This adaptive response allows the remaining kidney to ensure homeostasis and compensate for the lack of functioning contralateral renal tissue; however, the mechanisms behind compensatory renal growth remain poorly understood.

Insulin-like growth factor (IGF-1) appears to be an important mediator of compensatory renal hypertrophy (Cleper, 2012). IGF-1 is a growth factor that has a critical role in renal development, growth, and function (Kamenicky et al., 2013). Exogenous IGF-1 has been shown to increase GFR in normal humans (Guler et al., 1989) and attenuate renal injury resulting from obstruction in animals (Chevalier et al., 2000). IGF-1 levels are significantly elevated in the contralateral kidney after unilateral nephrectomy or after unilateral ureteral obstruction (Serel et al., 2000). Evidence suggests that IGF-1 expression may be increased in immature kidneys as compared with mature kidneys after unilateral nephrectomy (Mulroney et al., 1992). Significant increases in serum IGF-1 levels have also been demonstrated in humans after donor nephrectomy and IGF-1 levels have been positively correlated with the increased renal volume demonstrated on postoperative imaging after donor nephrectomy (Nam, Lee et al., 1999). Other growth factors have been implicated as effectors of this process (i.e. TGF-β1, hepatocyte growth factor [HGF]); however, the sensors of reduced renal mass that stimulate compensatory renal hypertrophy remain unknown.

Key Points: Functional Changes With Obstruction

- After obstruction, there is dysregulation of aquaporin water channels in the proximal tubule, descending loop, and collecting duct, which may contribute to long-term polyuria.

- The excretion of sodium after the relief of bilateral ureteral obstruction is greater than after UUO because in bilateral obstruction there is retention of sodium, water, urea, and other osmotic substances and an increase of atrial natriuretic factor, all of which stimulate a profound natriuresis.
- Recovery of renal function after relief of obstruction is affected by the duration, the degree, the patient's age, baseline renal function, collecting system compliance, and infection.
- Ureteral obstruction may result in prolonged decreases in concentrating ability, urinary acidification, and electrolyte transport long after the obstruction is released.
- Compensatory renal growth decreases progressively with increasing age. Although the kidney does enlarge, there is not an increase in nephrons or number of glomeruli after birth.

Treatment of Renal Obstruction

Pain Management

The first-line approach for the patient with renal colic is the administration of analgesics. Narcotics have a rapid onset of analgesia but may promote nausea and emesis, cause excessive sedation, and have the potential to be abused. Nonsteroidal anti-inflammatory drugs (NSAIDs) are nonopioid analgesics that, unlike narcotics, target the inflammatory basis of pain. Renal colic is thought to arise from increased collecting system pressure and an acute distention of the collecting system (Holmlund, 1983), and NSAIDs have been demonstrated to reduce collecting system pressure. Indomethacin, as well as other NSAIDs, cause a decrease in renal pelvic pressure in response obstruction (Frokiaer et al., 1993; Gasparich and Mayo, 1986; Sjodin et al., 1982) that is thought to be mediated by a reduction in renal blood flow. Perlmutter et al. (1993) demonstrated that ketorolac induces a prompt reduction in RBF and intrapelvic pressure in canines with UUO. COX-2 inhibitors are a form of NSAIDs that block the synthesis of prostaglandins from arachidonic acid. It has previously been shown that COX-2 inhibitors can prevent the PGE-mediated downregulation of aquaporin channels and major sodium channels in response to obstruction (Norregaard et al., 2005), and the resulting decrease in hydrostatic pressure within the tubules may provide an additional mechanism for the NSAID-mediated reduction in intrapelvic pressures.

In clinical trials, NSAIDs have proven to be superior to opioids in managing renal colic and are associated with a greater reduction in pain scores, less need for "rescue" analgesia, and less emesis than opioids (Holdgate and Pollock, 2004). **NSAIDs should not be used in patients with renal insufficiency, however, because renal dysfunction can be exacerbated by the decrease in renal blood flow induced by NSAIDs.** COX-1 inhibitors should also not be used in patients at risk for gastrointestinal bleeding or when optimal platelet function is needed, and COX-2 inhibitors have been linked to an increased risk of myocardial infarction and stroke because of an adverse effect on blood vessels (Cannon and Cannon, 2012). Although opioids have untoward side effects, they still provide excellent analgesia and remain an important tool in the management of the patient with renal colic. The administration of α_1-blockers (e.g., Flomax) have also been used for medical expulsive therapy and studies have demonstrated the ability of α_1-blockers to facilitate stone passage and reduce the requirement for analgesics (Wang et al., 2008).

Renal Drainage

Prompt drainage of the obstructed kidney is important to relieve pain and prevent functional decline. Minimally invasive endourologic and interventional radiologic techniques allow for temporary drainage until a definitive procedure can be performed or, in some circumstances, may be a permanent management option. Urine cultures should be obtained from the obstructed renal unit at the time of relief of obstruction when infection is suspected and antibiotic therapy should be instituted. Ureteral obstruction that is symptomatic, accompanied by fever, complicated by undrained infection, or determined to be high grade, bilateral, or inducing renal failure warrants immediate drainage.

Percutaneous nephrostomy (PCN) tubes and internal stents have been shown to be equally effective in relieving an obstructed collecting system with similar complication rates (Regalado, 2006). PCN tubes are larger caliber and offer the advantage of providing superior drainage, especially if the fluid is more purulent. The catheters can be irrigated to prevent clogging, the urine output of the kidney can be measured, and excessive ureteral manipulation can be avoided, decreasing the risk for sepsis or rupture. The procedure can also be done using ultrasound guidance with local anesthesia and conscious sedation, eliminating the need for an anesthesiologist and ionizing radiation exposure. Internal stents offer the advantage of increased patient comfort with no catheter extending out of the flank, and a lower potential risk for bleeding complications. Internal stent placement should therefore be considered first for patients that are coagulopathic. If thick, purulent fluid is obtained from the kidney at the time of ureteral stenting, placement of a large diameter stent is recommended and/or placement of an external diversion stent that can be irrigated and monitored. Internal stent placement typically requires greater x-ray exposure than percutaneous nephrostomy placement, which may be of concern in pregnant patients (McAleer and Loughlin, 2004; Mokhmalji et al., 2001), and accelerated stent encrustation in this patient population resulting from increased calcium excretion may increase the risk of stent failure (Goldfarb et al., 1989).

Historically, ureteral stenting has not been as effective for treating patients with extrinsic ureteral obstruction. Docimo and Dewolf (1989) reported a 43% failure rate in stents placed for extrinsic obstruction, the majority related to malignancy. Chung et al. (2004) similarly identified a 42% rate of stent failure in these patients, with a diagnosis of cancer, metastatic disease requiring chemotherapy or radiation, and renal insufficiency predictors of stent failure. **New metallic stents composed of a unique continuous unfenestrated coil of nonmagnetic alloy have been proven to be safe and effective for patients with extrinsic compression of the ureter and offer longer indwelling times (3.5 to 11 months).** Age and preoperative serum creatinine levels have been identified as independent risk factors for metallic stent failure, and lower GI cancers have been associated with longer metallic stent duration times than GU cancers (Chow et al., 2014).

Renal Recovery After Obstruction

A number of factors can affect the recovery of renal function after relief of obstruction, including the duration of obstruction, function of the contralateral kidney, age, pyelo-lymphatic backfIow, compliance of the ureter and renal pelvis, presence or absence of infection, and underlying renal disease (Soliman et al., 2011). **When acute complete ureteral obstruction is promptly relieved, full recovery of global GFR can occur, but longer periods of complete ureteral obstruction are associated with diminished return of GFR**. The persistent decrease in GFR and RBF after relief of obstruction is due to persistent vasoconstriction of the afferent arteriole. Vaughan and Gillenwater (1971) performed some of the initial studies on recovery of renal function after obstruction. In a canine model of UUO, researchers noted that full recovery of renal function occurred after 7 days of UUO, whereas only 70% recovery of GFR occurred after 14 days of UUO, 30% after 4 weeks of UUO, and no recovery occurred after 6 weeks of UUO. More recent studies have demonstrated that renal damage can persist despite recovery of renal function. After 3 days of UUO in a rat model of obstruction, GFR and RBF returned to baseline levels within 14 days in the previously obstructed kidney (Ito et al., 2004), but interstitial fibrosis and tubular apoptosis continued to increase after relief of obstruction. Mouse studies suggest that after 7 days of obstruction, normal renal function is not restored in the previously obstructed kidney even after 30 days of recovery, with GFR and RBF reduced by 40% and the urine albumin/protein ratio increased by 2.8-fold. The remaining intact nephrons are hypertrophied and there is evidence of substantial glomerular injury (Chaabane et al., 2013). In humans, delayed relief of obstruction (>2 weeks) has been demonstrated to decrease long-term renal function and increase the risk of hypertension (Lucarelli et al., 2013).

Complete reversal of renal damage is rarely achieved after release of complete obstruction in the neonatal kidney. Glick et al. (1984) **demonstrated that the functional salvageability of an obstructed fetal kidney is dependent on the duration of the obstruction and the gestational age at which the obstruction occurs. It has been demonstrated that glomerular numbers remain low 1 month after release of a 5-day period of complete obstruction, indicating a permanent loss in nephrons** (Chevalier et al., 1999)**. Although glomerular function initially improves with normalization of GFR 1 month after release of neonatal obstruction, GFR subsequently decreases by 80% 1 year after relief of obstruction secondary to progressive glomerular sclerosis** (Chevalier et al., 2000). Tubular deterioration is attenuated but not reversed after release of neonatal obstruction, and tubular function remains abnormal 1 month after release of obstruction, suggesting that renal transporter expression is not corrected after the release (Chevalier et al., 1999).

The presence of increased collagen deposition in the renal parenchyma at the time of pyeloplasty has been shown to have a negative impact on recovery of renal function, as it demonstrates a more advance state of renal fibrosis (Kim et al., 2005; Kiratli et al., 2008). **Thompson and Gough** (2001) **demonstrated that DMSA is superior to MAG3 and DTPA in measuring function of the obstructed kidney and predicting the ultimate outcome of surgical intervention**. MAG3 was found to underestimate the potential of the kidney for recovery and was associated with a large variation in accuracy. The superiority of DMSA in assessing function under these circumstances appears to be related to its fixation to the renal cortex and delayed clearance. In cases in which renal function is significantly depressed on diuresis renography and nephrectomy is being considered, a preoperative DMSA scan may be of additional value in surgical planning.

Choice of Surgical Intervention

Definitive management of urinary tract obstruction is based on the cause of obstruction, the status of the contralateral kidney, the function of the affected kidney, and the patient's age and overall medical status. A number of different endoscopic, open, laparoscopic, and robotically assisted ablative and reconstructive options are available and are discussed elsewhere in this text. In general, a nephrectomy should be considered for an obstructed kidney that contributes less than 10% to the patient's overall renal function. The decision to remove a kidney, however, should only be made after the kidney has been adequately drained for a sufficient period of time to allow maximal recovery and an accurate assessment of renal function (Kerr, 1954). In the setting of global renal insufficiency, the decision is more complicated, and patients may elect management with a chronic indwelling stent or nephrostomy tube to prevent more rapid progression to dialysis.

In children the determination of salvageability may also require a period of decompression and reassessment of relative function. Although no absolute cutoff for renal preservation exists, the typical threshold for function is between 10% and 15%. A large series of pediatric poorly functioning kidneys with less than 20% relative uptake were seen to have significant improvements in function after pyeloplasty (Menon et al., 2016). These authors recommend nephrectomy only when function is less than 5%. The initial assessment of relative renal function, usually by nuclear imaging, may not be completely accurate. Poorly functioning kidneys can improve their relative function after reconstruction; however, this may be only a limited amount, so parents should be provided with realistic expectations (Jiang et al., 2017).

Postobstructive Diuresis

Mechanism of Postobstructive Diuresis

Postobstructive diuresis, defined as a period of significant polyuria, may develop after the relief of urinary tract obstruction. Urine outputs of 200 mL or greater may be encountered. Although this primarily occurs after relief of BUO, it can rarely occur in the presence of a normal contralateral kidney (Roth et al., 2018; Schlossberg and Vaughan, 1984). The diuresis is generally a physiologic response to the accumulated solutes and volume expansion that has occurred during obstruction. Sodium, urea, and free water are eliminated, and the diuresis subsides after homeostasis is achieved. A pathologic postobstructive diuresis may also ensue, characterized by inappropriate renal handling of water and/or solutes. Downregulation of sodium transport channels (Li et al., 2003), downregulation of aquaporin channels (Li et al., 2001), poor responsiveness of the collecting duct to vasopressin, and altered regulation of ANP (Kim et al.,

2001) can result in a disruption of the medullary interstitial solute gradient and profound diuresis and natriuresis.

Postobstructive diuresis is uncommon in children but should be considered with relief of bilateral obstruction. It has been reported in neonates with unilateral obstruction, but this is uncommon (Boone and Allen, 1992; Roth et al., 2018).

Clinical Management of Postobstructive Diuresis

The majority of patients do not demonstrate a clinically significant postobstructive diuresis after relief of urinary tract obstruction, and those who are susceptible typically exhibit signs of fluid overload including edema, congestive heart failure, and hypertension. Most commonly, postobstructive diuresis develops after relief of urinary retention, and the speed at which the bladder is drained has not been shown to have any effect on the development of postobstructive diuresis or hematuria (Nyman et al., 1997).

After relief of obstruction, patients with BUO or an obstructed solitary kidney should be monitored for the development of postobstructive diuresis. Those patients with normal renal function, normal electrolytes, no evidence of fluid overload, and a normal mental status should have their vital signs and urine output monitored regularly and they should be given free access to oral fluids. If evidence of a postobstructive diuresis develops, vital signs, urine output, and electrolytes should be monitored more frequently, and patients should continue to have free access to oral fluids. Generally, patients with a normal mental status should not be given intravenous fluids, because this may prolong the period of diuresis. **This is a physiologic diuresis that, in the majority of cases, resolves when free water and excess solutes are eliminated.** In patients with impaired renal function, altered mental status, and signs of fluid overload, more intense monitoring is indicated. A urine osmolality should be checked, and vital signs and urine output should be checked frequently. Electrolytes should be monitored every 12 hours or more often if necessary. Patients with poor cognitive function should also be given intravenous fluids, although at a rate below maintenance. If a pathological diuresis ensues, the patient can become hypovolemic because of excess water loss and electrolyte abnormalities may develop as result of salt or potassium wasting. Very intense monitoring and careful fluid and electrolyte replacement is indicated in these patients. The urine is usually isosthenuric initially and intravenous fluid replacement with 0.45% saline administration at a rate lower than the urine output is recommended (Frokiaer and Zeidel, 2007). Changes in the type and amount of intravenous fluid administration are based on the patient's clinical status, serum, and urinary electrolytes.

Experimental Modulation of Postobstructive Diuresis

Experimental data do suggest the potential for pharmacologic manipulation of postobstructive diuresis. It remains unclear, however, what role pharmacologic manipulation may play in clinical practice. As discussed previously, BUO is associated with increased COX-2 expression, and selective COX-2 inhibition prevents the downregulation of AQP2 channels in response to obstruction (Norregaard et al., 2005). Norregaard et al. (2007) demonstrated that COX-2 activity increases in the postobstructive phase and that this contributes to polyuria and an impaired urine concentrating ability. After administration of a selective COX-2 inhibitor, the authors demonstrated that urine output was reduced but sodium excretion and GFR remained unchanged 24 hours after release of BUO. There is also evidence that sildenafil citrate (Viagra) can induce accumulation of AQP2 channels in collecting duct cells in vitro, independent of vasopressin stimulation, by activating a parallel cGMP-mediated pathway (Bouley et al., 2005). Clearly, further research is required to identify effective management strategies for postobstructive diuresis and to determine which patients would benefit from pharmacologic manipulation.

Key Points: Treatment of Renal Obstruction

- When acute complete ureteral obstruction is promptly relieved, full recovery of global GFR can occur, but longer periods of complete ureteral obstruction are associated with diminished return of GFR.
- Postobstructive diuresis is a result of (1) a physiologic diuresis that involves volume expansion and solute accumulation and (2) a pathological diuresis that involves derangements of the medullary gradient and transport processes for solutes in the renal tubule.
- Distended bladders should be expeditiously decompressed. There is no role for gradual decompression, because this does not limit hematuria or postobstructive diuresis.

Ectopic Ureter, Ureterocele, and Ureteral Anomalies

Irina Stanasel MD, Craig A. Peters MD

Classification and Anatomic Description

General Patterns

Abnormalities of ureteral development, including ectopic ureters and ureteroceles, represent a large component of clinical urology and continue to challenge clinical management in spite of their wide recognition and well-defined surgical strategies. The wide spectrum of clinical significance of these anomalies and the variable patterns of presentation underlie the clinical challenge and require a thorough understanding of both normal and abnormal embryology of the lower urinary tract. This chapter presents the embryologic pathology, clinical manifestations, and evaluation and management strategies for ectopic ureters and ureteroceles, as well as other less common ureteral anomalies. Obstructive ureteral pathologies including ureteropelvic junction (UPJ) obstruction and ureterovesical junction obstruction are reviewed in Chapter 42.

Although ectopic ureter and ureterocele are typically presented as distinct entities, it is apparent that they share many common features and may well have the same underlying developmental mechanisms, with slight variations that induce the very obvious differences in their appearances. In many ways, they may be approached in a similar manner, with slight variation in management because of their particular differences. It is also apparent that clinical cases may represent manifestations that lie between the two entities, suggesting a continuum of embryologic development.

Ectopic Ureter

By definition, an ectopic ureter is any ureter, single or duplex, that does not enter the trigonal area of the bladder. In a duplex system, this is inevitably the upper pole ureter, presumably because of its budding from the mesonephric duct later than the lower pole with later incorporation into the developing urogenital sinus. If it is simply near the bladder neck, it is not technically ectopic, which requires entry at the level of the bladder neck or distal. In females, the ectopic ureter may enter anywhere from the bladder neck to the perineum and into the vagina, uterus (Ghosh et al., 2016), and even rectum (Fig. 41.1). It may be associated with a cyst of the Gartner duct, the remnant of the Wolffian duct from which the ureter buds, and may include cystic dilation of the duct. The duct typically runs parallel to the vagina (the Müllerian structure), and with rupture of the cystic ductal structure, communication with the vagina is established. This is the basis for incontinence, the frequent presentation of an ectopic ureter in females. In males, the ectopic ureter always enters the urogenital system above the external sphincter or pelvic floor, and usually into the Wolffian structures, including the vas deferens, seminal vesicles, or ejaculatory duct (Fig. 41.2; also see Fig. 41.1). Presentation in male patients does not involve incontinence, but rather infection and pain of the affected organs (testicles and epididymis). When associated with an ipsilateral renal absence and seminal vesicle cyst, it is termed *Zinner syndrome* (Ghonge et al., 2010; Haddock and Wagner, 2015).

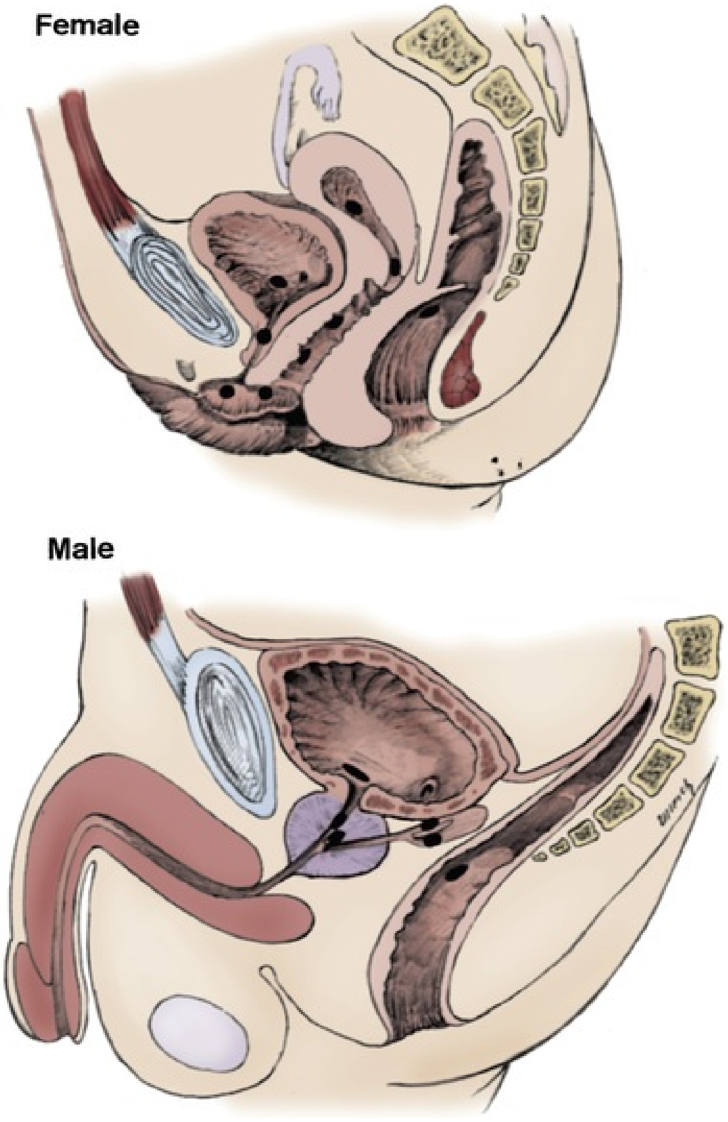

FIG. 41.1 Sites of ectopic ureteral orifices in the male and female.

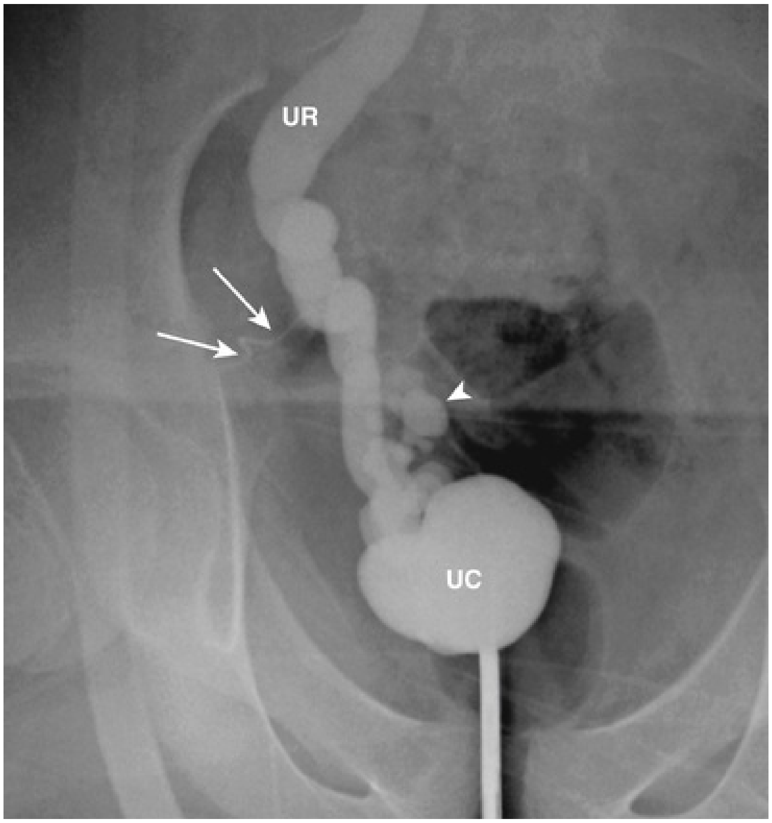

FIG. 41.2 Retrograde injection study of a boy with abdominal pain and a ureterocele associated with a hypoplastic right kidney. The intravesical ureterocele *(UC)* is being injected and demonstrates communication with the right seminal vesicle *(arrowhead)* and vas deferens *(arrows),* with the ureter *(UR)* leading to the dysplastic kidney. At surgical resection, the ureter and vas were joined just above the seminal vesicles.

Single-system ectopic ureters and ureteroceles may manifest in a similar fashion to the ectopic upper pole but may also be associated with an apparently absent kidney. This usually reflects an inability to identify the kidney using ultrasound and has led to the use of computed tomography (CT) imaging with contrast or renal function studies to detect small, poorly functioning renal units associated with an ectopic ureter (Borer et al., 1998). Either single or duplex systems with an ectopic ureter may be associated with severe hydronephrosis reflecting distal obstruction. Severe obstruction may have impaired normal renal development to the point that the affected segment is nonfunctional.

The rare entity of bilateral single-system ectopic ureters may be associated with a hypoplastic bladder and a poorly developed trigone and bladder neck, as well as with bilateral renal abnormalities, typically dysplasia (Koyanagi et al., 1977; Noseworthy and Persky, 1982; Johnin et al., 2007).

Key Points: Ectopic Ureter

- An ectopic ureter is any ureter, single or duplex, that does not enter the trigonal area of the bladder.
- In a duplex system, the ectopic ureter is inevitably the upper pole ureter. This is because budding from the mesonephric duct occurs later (more cephalad) than the lower pole ureteral bud.
- In females, the ectopic ureter may enter anywhere from the bladder neck to the perineum and into the vagina, uterus, and even rectum. One of the classic symptoms is continuous wetting.
- In males, the ectopic ureter always enters the urogenital system above the external sphincter or pelvic floor and usually into the Wolffian structures, including the vas deferens, seminal vesicles, or ejaculatory duct. Clinical presentation is not incontinence.

Ureterocele

Ureteroceles represent a version of the ectopic ureter with a cystic dilation of the distal aspect of the ureter that is located either within the bladder or spanning the bladder neck and urethra. As with the ectopic ureter, ureteroceles may be associated with a single or duplex system, and in duplex systems are associated with the upper pole (Fig. 41.3). Ureteroceles can extend into the urethra but do not form entirely within the urethra, nor do they attach to the Wolffian ductal structures.

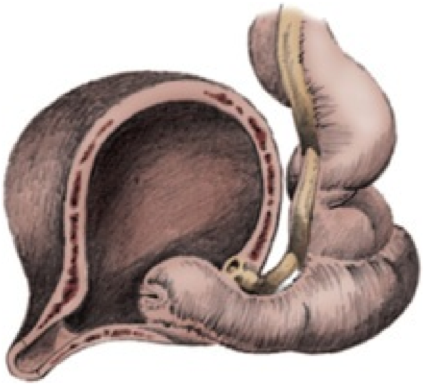

FIG. 41.3 Diagram of intravesical ureter with stenotic orifice just proximal to the bladder neck.

Several classification systems exist for ureteroceles, but the most useful one for clinical practice separates intravesical from extravesical ureteroceles. The intravesical ureterocele is entirely within the bladder and above the bladder neck. This would include a "simple" ureterocele that may be seen in the adult with mild to no upper tract dilation, suggestive of lack of obstruction. This term, however, should be discouraged as it can be confusing; the term *single intravesical ureterocele* should be used in its place (Glassberg et al., 1984). Intravesical ureteroceles can also present with obstruction, severe hydronephrosis, and clinically significant sequelae. Ectopic ureteroceles include those "in which some portion of the ureterocele is situated permanently at the bladder neck or urethra" (Glassberg et al., 1984). The orifice may be in the bladder, at the bladder neck, or in the urethra. This should be distinguished from an intravesical ureterocele that prolapses into the urethra with voiding.

Other notable classifications of ureteroceles have been published (Stephens, 1971). This classification includes cecoureteroceles and stenotic, sphincteric, sphincterostenotic, blind, and nonobstructed ureteroceles (Fig. 41.4). From a clinical perspective, it is critical to recognize the subgroup of cecoureteroceles. In these cases, the orifice of the affected ureter is within the bladder, but the cavity of the ureterocele extends submucosally beyond the bladder neck into the urethra. These may not be readily characterized preoperatively (Smith and Parrott, 1994), and their complexity may create surgical challenges, particularly with endoscopic incision (see later).

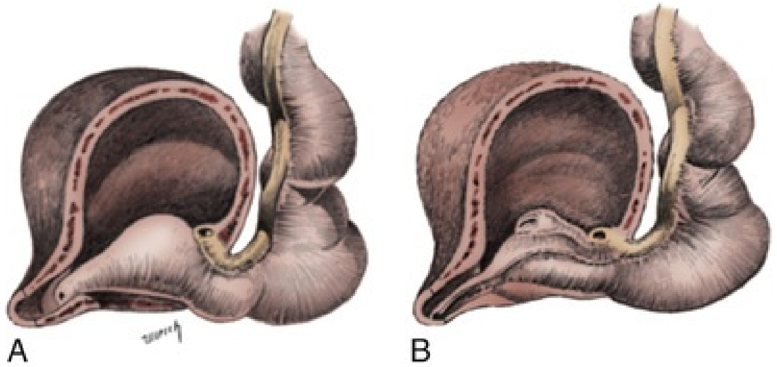

FIG. 41.4 (A) Sphincterostenotic ectopic ureterocele. (B) Cecoureterocele lumen extends distal to the orifice as a long tongue beneath the ureteral submucosa. The orifice communicates with the lumen of the bladder and is large and incompetent.

An unusual but diagnostically challenging ureterocele variant is the nonobstructive ureterocele with duplication (Bauer and Retik, 1978) or “ureterocele disproportion” (Share and Lebowitz, 1989) (Fig. 41.5). These are associated with a duplex kidney, but the affected upper pole is nondilated and typically dysplastic to such a degree that it is not readily detected on most imaging, and the affected ureter is not dilated beyond the bladder. A typical-appearing ureterocele is seen in the bladder, but the ipsilateral kidney appears completely normal.

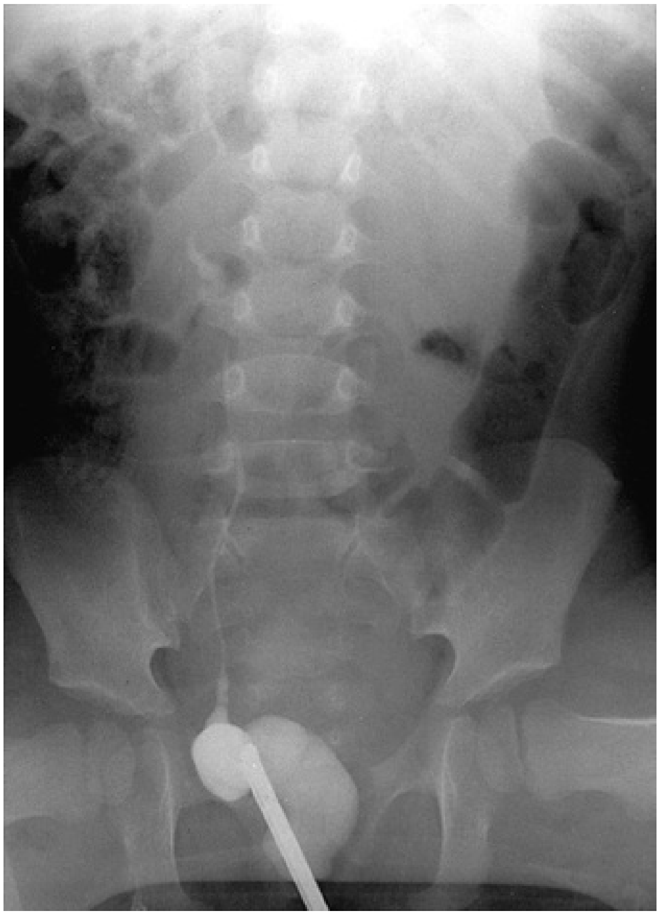

FIG. 41.5 Retrograde pyelogram demonstrating ureterocele disproportion. Note the disparity between the large ureterocele and the thin ureter and nondilated collecting system.

There is some association of ureterocele type with outcomes of various therapeutic measures, but these predictions have not proven to be as reliable as initially reported. Churchill et al. proposed a classification system based on the impact of the ureterocele on the upper urinary tract that included the impact on all of the patient's renal units (Churchill et al., 1992). This functional system separates those in which the upper pole only is in jeopardy, those in which an entire ipsilateral kidney is threatened, and those in which the contralateral system is also at risk because of reflux or bladder outlet obstruction. The last group comprised 26% of the reported cases.

Key Points: Ureterocele

- Ureteroceles represent a version of the ectopic ureter with a cystic dilation of the distal aspect of the ureter that is located either within the bladder or spanning the bladder neck and urethra.

- Several classification systems exist for ureteroceles, but the most useful distinction for clinical practice separates intravesical from extravesical ureteroceles.
- Cecoureteroceles are ones in which the orifice of the affected ureter is within the bladder, but the cavity of the ureterocele extends submucosally beyond the bladder neck into the urethra.

Embryology and Etiology

The specific mechanisms responsible for development of ectopic ureters and ureteroceles remain undefined, but our emerging understanding of normal and abnormal ureterotrigonal development is likely to provide valuable insights (Mendelsohn, 2009). This work provides insight into the cellular basis of renal branching morphogenesis and demonstrates that both *Ret*-dependent cell movements and *Ret*-independent changes in the Wolffian duct epithelium contribute to ureteric bud formation. These molecular mechanisms are of scientific importance and will hopefully permit potential separation among variants of these conditions with therapeutic relevance, as well as ultimately permitting early detection (i.e., in utero) and intervention. At the present time, we remain uncertain as to the fundamental mechanisms, and we need to know which ureteroceles and ectopic ureters are associated with bladder neck and trigonal maldevelopment sufficient to cause functional disturbances such as incontinence. Early identification may lead to early diagnosis and prevention of complications such as infection and renal scarring, as well as early and more effective surgical therapies.

Ureteral-Trigonal-Renal Development

The pathogenesis of ureteral ectopia with or without ureterocele results in renal maldevelopment caused by defective ureterotrigonal connections. At the present time, a growing number of genetic pathways have been identified that are critical in humans and rodents for establishing distal ureter connections, and studies in mouse models have led to a better understanding of the process by which proper distal ureter connections are generated.

Function of the urinary tract depends on patent ureterobladder connections and an antireflux mechanism that prevents backflow of urine to the ureter and kidneys. The antireflux valve is formed by intersecting ureteral and bladder muscle fibers. Therefore, malpositioned ureters that do not follow a precise trajectory through the bladder wall or terminate outside the normal insertion site in the trigone can cause obstruction or vesicoureteral reflux (VUR). Renal defects associated with ureteral ectopia or ureterocele can be caused by obstruction that damages renal cell types (see Chapter 40) or mutations in genes that are required independently for normal kidney development and ureter insertion, including *RET*, *FGFR2*, and *GATA3* (Chia et al., 2011; Liu et al., 2011; Hoshi et al., 2012).

Classic understanding of ureterotrigonal development teaches that the trigone originates from the mesodermal common nephric duct (CND), as do the mesonephric duct and thus ureter, and is distinct from the urogenital sinus, which is of endodermal origin. According to this model, proper ureterobladder connections depend on expansion of the CND and its subsequent insertion into the urogenital sinus epithelium (UGE), both separating the CND and ureter and producing a mature insertion site in the bladder (Wesson, 1920; Tanagho and Pugh, 1963; Woodburne, 1965). However, the observation that the CND degenerates during ureter maturation suggests that the CND may not give rise to the trigone as previously thought (Batourina et al., 2002, 2005; Viana et al., 2007; Chi et al., 2009; Mendelsohn, 2009; Uetani et al., 2009; Tanaka et al., 2010). Consistent with this, lineage studies and tissue recombination studies in mice suggest that the trigone is formed by interconnections between the detrusor and fibers surrounding the intravesical ureter (Viana et al., 2007).

With ureteral bud formation, the mesonephric duct becomes the CND caudally toward the insertion into the urogenital sinus. Studies in animal models indicate that establishing a mature ureterobladder connection depends on a process of ureteral maturation, a complex series of events driven by cellular rearrangements and apoptosis of the CND. Ureteral maturation begins when the most distal portion of the CND begins to merge with the urogenital sinus and undergoes apoptosis, which occurs over the course of several days. This first round of apoptosis results in removal of the most distal portion of the CND and formation of a loop composed of the remaining CND and distal ureter. The loop makes contact with the dorsal UGE, an event that sets the position of the future ureter orifice. Merger of the loop with the UGE and removal of the remaining CND by apoptosis generates a patent connection between the ureter and bladder, which at this stage is at the level of the verumontanum. Subsequent growth and expansion of the bladder and urethra further separate the mesonephric duct and distal ureter. The ureter is initially occluded by cells that undergo apoptosis (Mendelsohn, 2009). These cells correspond to the Chwalle membrane, which in humans is thought to be important for generating a patent ureterobladder connection. If the process of apoptosis is abnormal, this is thought to result in formation of a ureterocele (Chwalle, 1927).

Studies in mouse models suggest that ectopic ureters can arise from defects that cause misalignment of the loop with the dorsal side of the urogenital sinus, altering the position where the ureteral orifice inserts. Potential events include delayed or defective nephric duct insertion into the cloaca, sprouting of the primary ureteric bud from an abnormally high or low position on the nephric duct relative to the urogenital sinus, and defective ureteral maturation. A ureter that inserts in the proper site but is obstructed may reflect failure in regression of the Chwalle membrane. The revised model of ureteral maturation provides possible mechanisms for ureteral ectopia and ureterocele formation. Abnormal apoptosis may maintain the connection between the ureter and the Wolffian duct and prevent incorporation of the ureter and the urogenital sinus. This defect would produce a ureter attached to the Wolffian remnants in girls (Gartner duct) or to the vas deferens or ejaculatory system in boys. Alternately, partial CND regression may result in ureters that join the bladder at an abnormally posterior site, close to or in the urethra.

In duplicated systems, upper pole kidneys derived from ureteric bud branches that formed at an abnormally high position on the mesonephric duct tend to be obstructed, whereas distal ureteral obstruction is rare in lower pole renal moieties that arise from ureteric bud branches that sprout from the mesonephric duct at the appropriate site. This upper pole defect may reflect incomplete CND remodeling, a suggestion supported by observations from mouse models with duplicated systems. In this case, CNDs associated with ureters that form at an abnormally anterior site on the mesonephric duct persist, resulting in obstruction, whereas CNDs associated with ureters that form at the proper site, close to the urogenital sinus, undergo regression. These observations together suggest that signals from the urogenital sinus may normally regulate ureteral maturation by controlling CND remodeling.

These observations suggest that the final position of the ureter depends in large part on the extent of CND remodeling, which can be disrupted by defects in cell movements or apoptosis. If there is no remodeling, the ureter will remain joined to the sex duct (ectopic vas deferens or Gartner duct in girls). Partial CND remodeling could produce a different defect. In this case, distal ureters will be joined to the urogenital sinus at a site that is closer to the nephric duct, which joins at the level of the verumontanum or sinus ridge. Very similar defects are observed in mouse models, including mutants lacking *Ret*. Mutations in *RET* in humans cause Hirschsprung disease, renal abnormalities, VUR, and hydronephrosis. Studies in *Ret*-mutant mice indicate that *Ret* controls ureteric bud formation as well as mesonephric duct insertion and CND regression, suggesting that conserved genetic pathways may be required at independent sites and at different stages for generating a normal urinary system.

Obstruction is unlikely to be a major, and certainly not the only, factor producing ureteral dilation as seen with ureteroceles. Ureteroceles with large orifices and no apparent obstruction are well recognized clinically. Ectopic ureters with insertion into the bladder neck are dilated, but do not have the disproportionate distal dilation characteristic of the ureterocele. Obstruction plays some role in ureterocele pathophysiology, however, as is evident in the frequent occurrence of decompression with ureterocele puncture. Whether this is determined by the degree of muscularization of the ureterocele is undefined. Recent studies support the idea that degeneration of the Chwalle membrane is important for generating a patent connection between the ureter orifice and the bladder (Chwalle, 1927; Mendelsohn, 2009). These studies suggest that the Chwalle membrane, which has been thought to form from the urogenital sinus, may in fact be derived from luminal cells in the ureter that undergo apoptosis at a relatively late stage, before the onset of renal function, which may be important for generating a patent connection between the distal ureter and bladder.

Key Points: Embryology

- In contrast with the classic model in which the CND forms the trigone, the revised model includes regression of the CND in the normal animal through apoptosis and formation of the trigone from the endoderm, like the bladder.
- The classic explanation of ureterocele formation is that of Chwalle, who postulated that distal ureteral expansion is produced by failure of rupture of a distal membrane at the ureteral orifice (Chwalle membrane).
- Because the ureteral bud derives from the Wolffian duct, the ectopic ureter

will not insert directly into the Müllerian structures (vagina, cervix, uterus), but will be associated with them through the remnant of the Wolffian duct, the Gartner duct, which runs alongside the mature Müllerian structures.

- The Weigert-Meyer rule describes the inverse relationship of the duplex ureteral orifices, in which the ectopic ureter or ureterocele associated with the upper pole is caudal to the lower pole ureteral orifice.

Clinical Presentation

Imaging

Prenatal Detection

The majority of ureteroceles and ectopic ureters are detected through prenatal ultrasound imaging, even if only through the identification of hydronephrosis. The abnormality prompts postnatal imaging, leading to better characterization of the condition. The prenatal imaging patterns are identical to those seen postnatally on ultrasound imaging, but are more easily misinterpreted on prenatal imaging. Although these are described in Chapter 22, several elements should be emphasized.

The identification of a duplex system may be difficult except when one of the moieties is dilated. The report of an upper pole "cyst" in a fetus should be interpreted as being upper pole hydronephrosis until proven otherwise. Minor degrees of hydronephrosis may not be readily identified, although changes over time may prompt recognition. The expected ureteral dilation may not be readily detected but can often be traced to the bladder. The bladder must be inspected in all such cases to identify a ureterocele, but it may be necessary to await bladder filling to make this observation. A large ureterocele can fill a bladder and mask its own presence.

The character of the renal parenchyma of the upper pole should be noted, both thickness and echogenicity. The findings may be useful in making clinical decisions.

The ectopic ureter can appear identical to a ureterocele except at the bladder level, with a dilated upper pole and tortuous ureter but no intravesical component. On occasion, a large ectopic ureter may impinge on the bladder and appear as an intravesical structure, termed a *pseudoureterocele* (Sumfest et al., 1995). These patterns are identical to the postnatal appearance, but their recognition does require an experienced maternal-fetal ultrasonographer.

With a tentative diagnosis of a ureterocele or ectopic ureter, careful evaluation of the other renal units and bladder should be made. Ipsilateral lower pole or contralateral dilation suggests reflux or less commonly obstruction from the ureterocele or the dilated ectopic ureter. Bladder outlet obstruction by a ureterocele can occur and manifest as hydronephrosis and possibly obstruction of all renal units (Ogunyemi, 2001; Quintero et al., 2001; Godinho et al., 2013).

Although it is very unusual to identify bladder obstruction from a ureterocele to the extent of producing oligohydramnios, this can occur. Contralateral renal dysplasia may be evident and associated with reduced amniotic fluid. The need for prenatal intervention or early delivery is exceptional and unlikely to provide significant benefit.

A single-system ureterocele or ectopic ureter is suggested by dilation of the entire kidney and ureter. It may be impossible to differentiate this from an obstructive megaureter or severe reflux, but this has little immediate prenatal clinical impact, and differentiation can be made postnatally with additional studies.

Incidental Postnatal Detection

Ectopic ureters and ureteroceles are sometimes diagnosed based on findings of hydronephrosis when imaging studies are performed for unrelated reasons such as trauma or abdominal pain. In some cases, the studies are performed for general abdominal pain that was not considered to have a renal cause but may in fact prove to be of renal origin. It is also possible that the dilated ureter may not be recognized as such. Cases of presumed ovarian cysts have been seen that were actually markedly dilated ureters, so it is important to consider the dilated ureter as part of the differential when diagnosing dilated structures in the pelvis (Mason et al., 2012).

Infection

Infection remains a significant reason for clinical presentation of both ectopic ureters and ureteroceles, which may occur at any age and have a highly variable pattern.

Although there is great variability in the presentation of either ectopic ureter or ureterocele, there are several patterns that may be anticipated. In either case, generalized urosepsis may be the presenting clinical scenario, and renal bladder ultrasonography will usually provide the diagnosis. It has been reported that an acute ultrasound study is unnecessary if a child has a febrile urinary tract infection (UTI) and a history of a normal prenatal ultrasound examination after 30 to 32 weeks (Hoberman et al., 2003). The extreme variability of quality of prenatal imaging makes this recommendation tenuous, and it would seem prudent that an ultrasound study be obtained in all children with urosepsis. In those with a febrile UTI, there is rarely urgency if they are clinically responding.

The value of early detection is the potential for early treatment, which may be a simple drainage procedure.

In the acute setting, with evidence of an ectopic ureter or ureterocele, initial clinical response will determine the timing of intervention. Certainly the child with sepsis who is not responding rapidly to appropriate therapy may require urgent transurethral incision (TUI) of an infected ureterocele or percutaneous or open drainage of an ectopic ureter. Open drainage in this setting is often an end ureterostomy as described later.

Ectopic ureters will frequently manifest with a less acute pattern evidenced by ongoing low-grade fever with periodic spikes. In some cases, a negative urine culture will be present simply because the infected ectopic system is not draining into the bladder. Parents may describe a purulent discharge from the perineum (See and Mayo, 1991). This clinical pattern should prompt an ultrasound study, which will usually reveal a dilated upper pole or entire system. It is rare for the unobstructed ectopic ureter to manifest with infection, but it can be associated with incontinence.

In boys, a similar generalized subacute pattern of infection may be present, but more often these boys have epididymitis on presentation. Although this may be an unusual subset of young boys with an acute scrotum, they can have a true bacterial epididymitis or infected urine. In the setting of suspicion for epididymitis in a young boy, it is prudent to perform a brief ultrasound examination of the upper tracts to ensure no abnormality (Rajfer et al., 1978; Umeyama et al., 1985; Chu et al., 2012). Older males will also present in this manner, although it is unclear why it may be so delayed. Some have had recurrent episodes of epididymitis before the underlying cause is detected.

Incontinence

Urinary incontinence may be caused by an ectopic ureter in a girl, but not in a boy. Untreated ureteroceles are not associated with incontinence. The toilet-trained girl with verified continuous urinary leakage must be evaluated for an ectopic ureter. Imaging studies may not immediately detect this condition because the affected renal moiety may not be dilated, and the level of suspicion must be guided by a careful history and occasionally physical examination. Before toilet training, it may be difficult to detect continuous incontinence, although some parents will note persistent dribbling during changing. In early training, the wetting may be falsely attributed to lack of motivation. Persistence should prompt evaluation, and the characteristic history can be obtained. This is usually one of persistent low-volume dampness at all times. When asked if the child can be dry for 30 to 60 minutes, the parent will usually say no. It is important to be cautious in questioning, because some parents with children who wet for other reasons may state, “She is always wet,” when in fact the child can be dry for periods. The dampness associated with an ectopic ureter typically occurs throughout the day and night and does not relent. It may seem to worsen with activity in some patients. In rare patients, it can be intermittent, perhaps caused by intermittent leakage through a membrane of the Gartner duct.

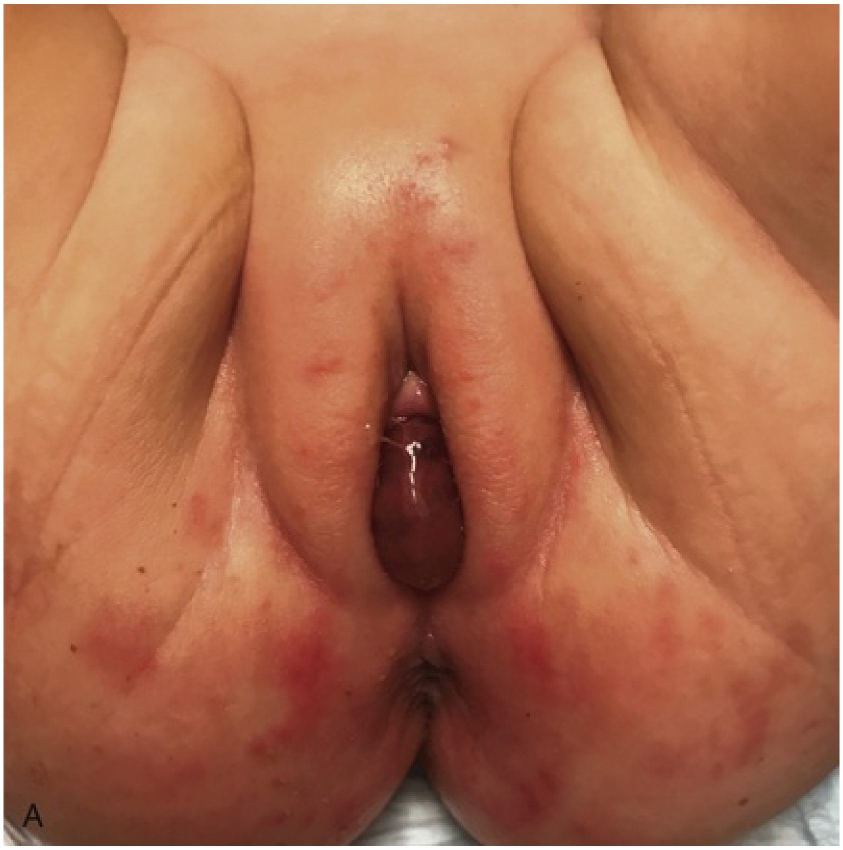
In older children in whom the diagnosis has not been recognized, attribution of the symptoms may be to dysfunctional voiding, laziness, and even sexual abuse (Lane, 1962; Carrico and Lebowitz, 1998). During the history taking, signs of typical voiding dysfunction such as voiding postponement, posturing, and constipation should be sought to assess the likelihood of these being an explanation for the wetting.

Pain

Pain is uncommonly associated with either an ectopic ureter or a ureterocele. The exceptions are pain related to acute infection, episodic obstruction of the ectopic ureter, and bladder pain caused by an obstructing ureterocele. Occasional cases of intermittent drainage of an ectopic ureter in older children have been described and are characterized by abdominal pain followed by perineal drainage of urine or purulent material. It is presumed that this reflects accumulation of urine in a system that is obstructed at the level of the orifice with subsequent drainage and relief of symptoms.

Prolapse

Ureterocele prolapse is an unusual but distinctive presenting sign that may still confuse the clinician. These are usually smooth, congested mucosal-covered interlabial masses, and the child may be experiencing difficulty voiding. The mass protrudes from the urethra, distinct from the vagina. It is not lobulated as a sarcoma botryoides would appear. An ultrasound examination of the bladder will usually confirm the diagnosis, and kidney images will further support this (Fig. 41.6A and B).



A

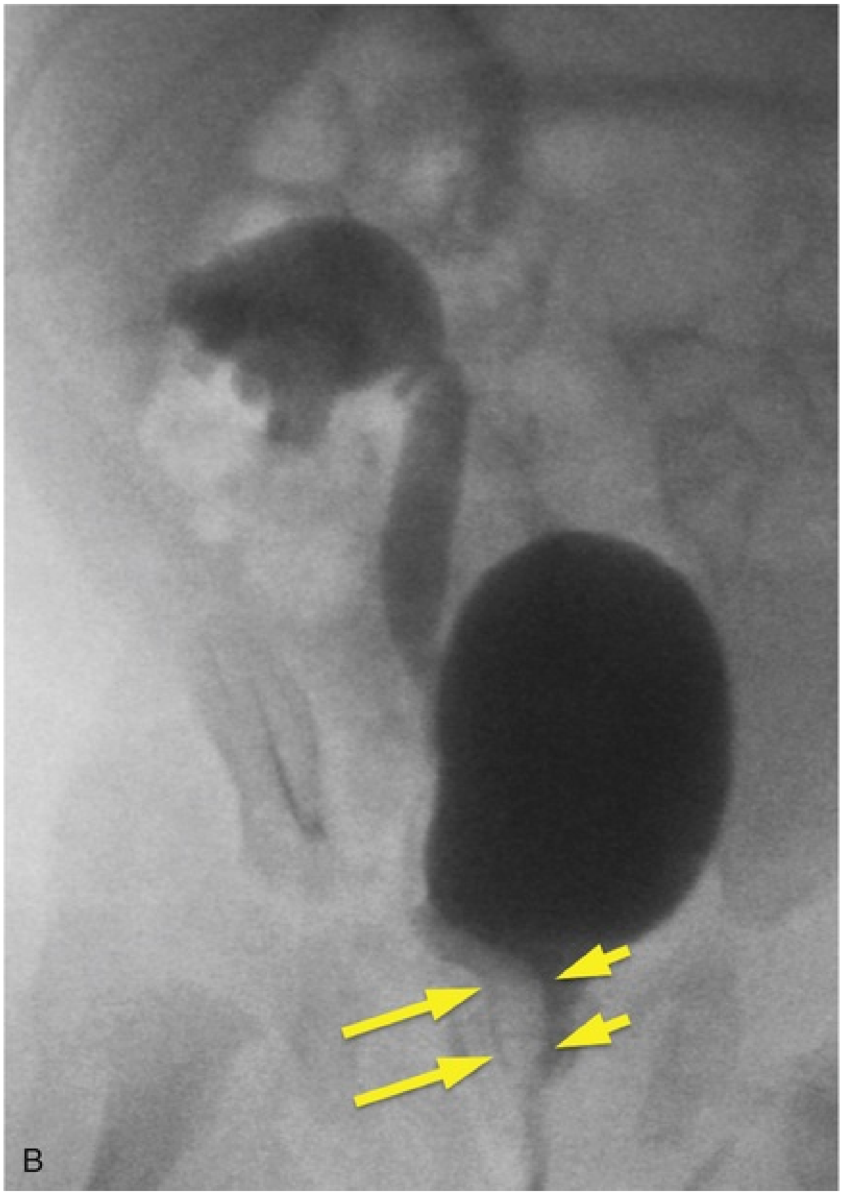


FIG. 41.6 (A) A prolapsed ureterocele presented as an interlabial mass in a 14-month-old girl. (B) Voiding cystourethrogram demonstrates the ureterocele prolapsing into the urethra *(arrows)* with associated lower pole reflux and the classical "drooping lily" appearance of the lower pole, displaced by the dilated upper pole. The prolapse was reduced in the operating room and the ureterocele incised.

Late Presentation

Presentation of both ectopic ureters and ureteroceles in the teen or adult has been reported, usually associated with infection or abdominal pain and rarely incontinence (Idbohrn and Sjostedt, 1954; Abrahamsson et al., 1981; Amitai et al, 1992; Westesson and Goldman, 2013). The nonobstructing ureterocele, often associated with a single system, is well recognized in the adult, often with a stone in the small ureterocele (Singh, 2007; Mizuno et al., 2008). Vaginal wall prolapse has also been associated with an ectopic ureter (Chai et al., 2014). Ureterocele prolapse after incision in adults has been reported (Campobasso et al., 2018). There is usually little to no function associated with the affected renal moiety, and although extirpative therapy with upper pole heminephrectomy has been the mainstay of treatment in these cases, upper to lower pole ureteroureterostomy may also be considered (Brehmer et al, 2007; Mason et al., 2012).

Key Points: Clinical Presentation

- The majority of ureteroceles and ectopic ureters are detected by prenatal ultrasound imaging based on the presence of hydronephrosis, although a specific diagnosis is often not made until after birth.
- Ectopic ureters frequently manifest with a less acute pattern evidenced by ongoing low-grade fever with periodic spikes. In some cases, urine cultures are negative because the infected ectopic system is not draining into the bladder.
- Boys with ectopic ureter can present with a subacute pattern of infection but often have associated epididymitis.
- Urinary incontinence may be caused by an ectopic ureter in a girl but not in a boy.
- The toilet-trained girl with verified continuous urinary leakage must be evaluated for an ectopic ureter.
- Ureterocele prolapse is an unusual but distinctive presenting sign; these are usually smooth, congested mucosa-covered interlabial masses, and the child may experience difficulty voiding.

Evaluation

Management of ectopic ureter or ureterocele is based on a thorough assessment of the affected anatomy and the functional implications of the condition.

Anatomic Assessment

Physical Examination

Physical examination provides invaluable information for the diagnosis of both ectopic ureter and ureterocele. The prolapsed ureterocele is diagnostic and dramatic, but unusual. Further study of the detailed anatomy is necessary. It is unusual to be able to detect an ectopic perineal ureteral orifice in a child, but this does provide much information as to the character of the situation and best treatment when it is identified (Fig. 41.7). A search for the perineal orifice in a child with continuous wetting or a known leaking ectopic ureter is worthwhile. Rarely, the dilated Gartner duct cyst may be detected on careful perineal examination (Fig. 41.8). These orifices or cystic structures may then be imaged by injection of contrast.

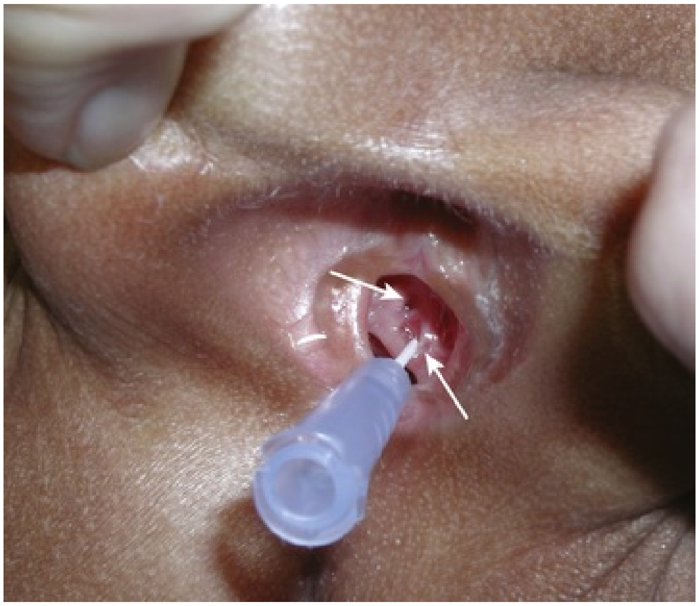

FIG. 41.7 Perineal ectopic ureteral orifice *(bottom arrow)* cannulated with an angiocatheter, situated between the urethral orifice *(top arrow)* and the vagina, just to the left of midline.

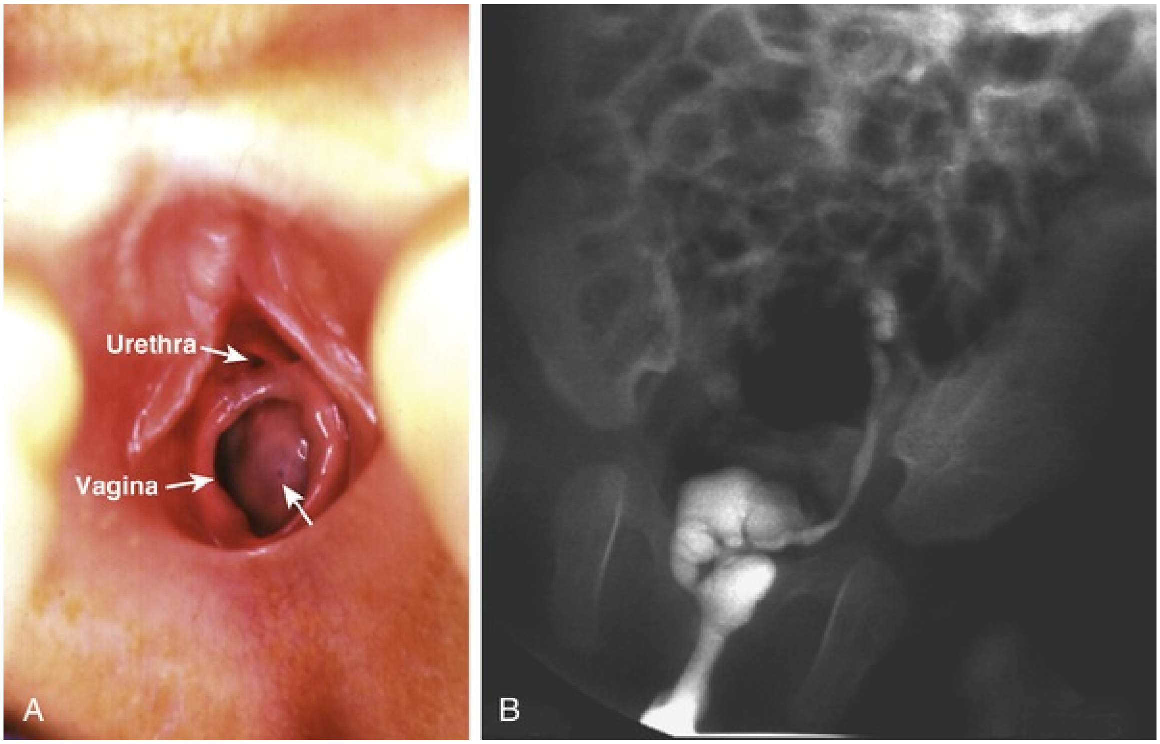

FIG. 41.8 (A) Gartner duct cyst *(bottom right arrow)* in a newborn with a left multicystic dysplastic kidney. (B) Injection of the cyst communicated with the ureter and dysplastic kidney.

The dilated upper pole of either an ectopic ureter or ureterocele may be palpable in the relaxed infant, but this is difficult in the older child.

Ultrasonography

The ultrasound image will usually provide the anatomic diagnosis and permit inference of functional assessment. **The typical findings are as with the prenatal imaging of a dilated upper pole with ureteral dilation or a dilated single system.** The character of the renal parenchyma is more readily seen postnatally, and if it appears healthy, the true need for functional upper tract imaging is controversial. Depending on the chosen treatment algorithm, it may be argued that this is unnecessary if it will not change treatment. The difference between functioning upper poles and those with little to no function is usually apparent (Figs. 41.9 and 41.10).

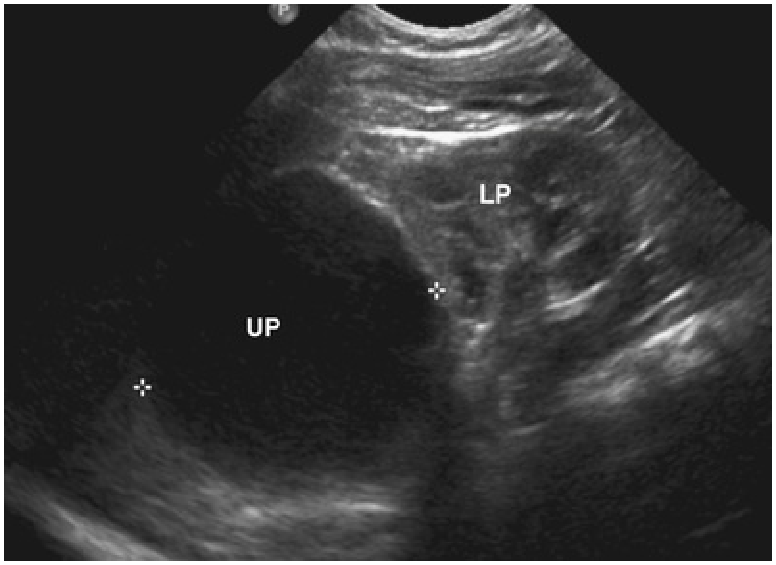

FIG. 41.9 Ultrasound image of dilated upper pole *(UP)* associated with a ureterocele, demonstrating limited renal parenchyma (same patient as in Fig. 41.33). *LP,* Lower pole.

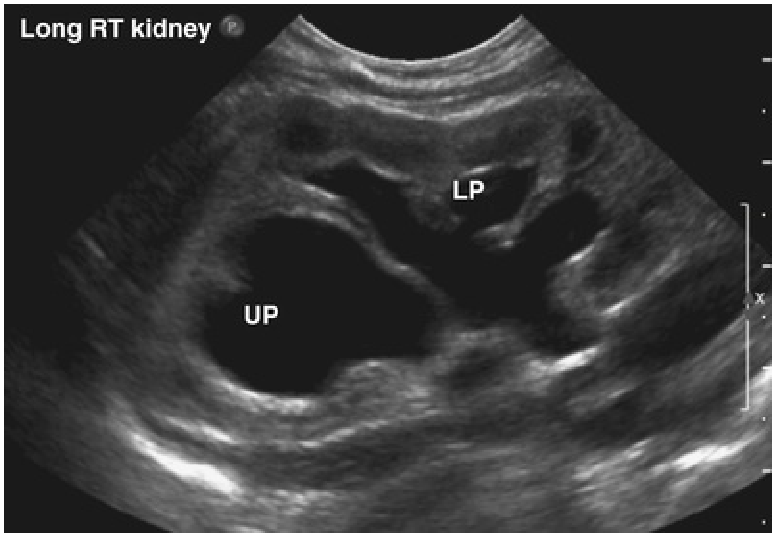

FIG. 41.10 Ultrasound image demonstrating dilated upper pole *(UP)* and lower pole *(LP)* associated with a ureterocele. The upper pole has evident renal parenchyma. The lower pole is dilated because of compression of the dilated upper pole ureter on the lower pole system, creating a partial obstruction.

There are no characteristics that permit differentiation between a dilated ectopic ureter and ureterocele above the level of the bladder. **The bladder images therefore are critically important because management of the two**

entities can be very different.

Bladder views are typically diagnostic in differentiating ureterocele from ectopic ureter by revealing a thin-walled, cystic dilation within the bladder and not extending beyond its walls (Fig. 41.11). The laterality of the ureterocele is usually apparent but may appear midline if large. A lobulated ureterocele may appear as two structures, but careful examination should show communication. It is difficult to visualize extension of a cecoureterocele into the bladder neck, so nonvisualization is not diagnostic.

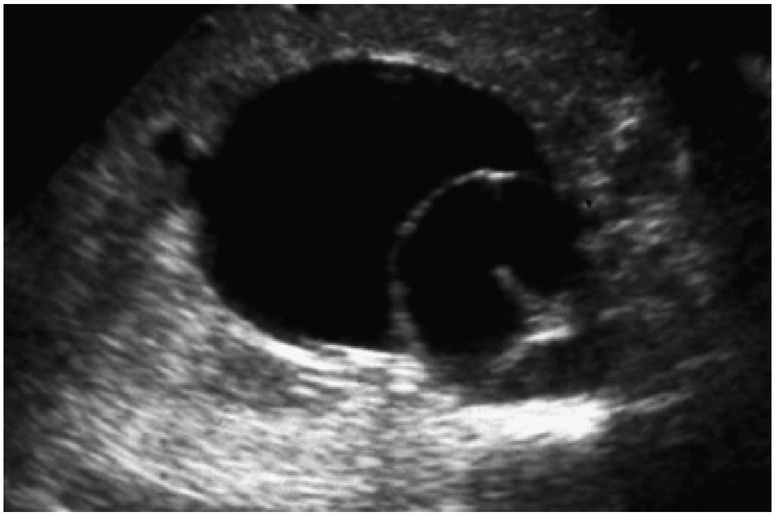

FIG. 41.11 Ultrasound image of an intravesical ureterocele at the bladder level.

Several ultrasound patterns may produce confusion in diagnosis. A large ureterocele may completely fill a bladder with no urine in the bladder itself. A full bladder with an effaced ureterocele may be mistakenly considered an ectopic ureter. Observation of the bladder over time will usually avoid these errors. A very dilated ectopic ureter may produce an impression on the bladder and appear as a ureterocele, but the wall will be bilaminar and much thicker than typically seen with a ureterocele (Fig. 41.12A and B). Furthermore, the lumen of the ectopic ureter will extend well outside the bladder walls. This is referred to as a pseudoureterocele as mentioned earlier.

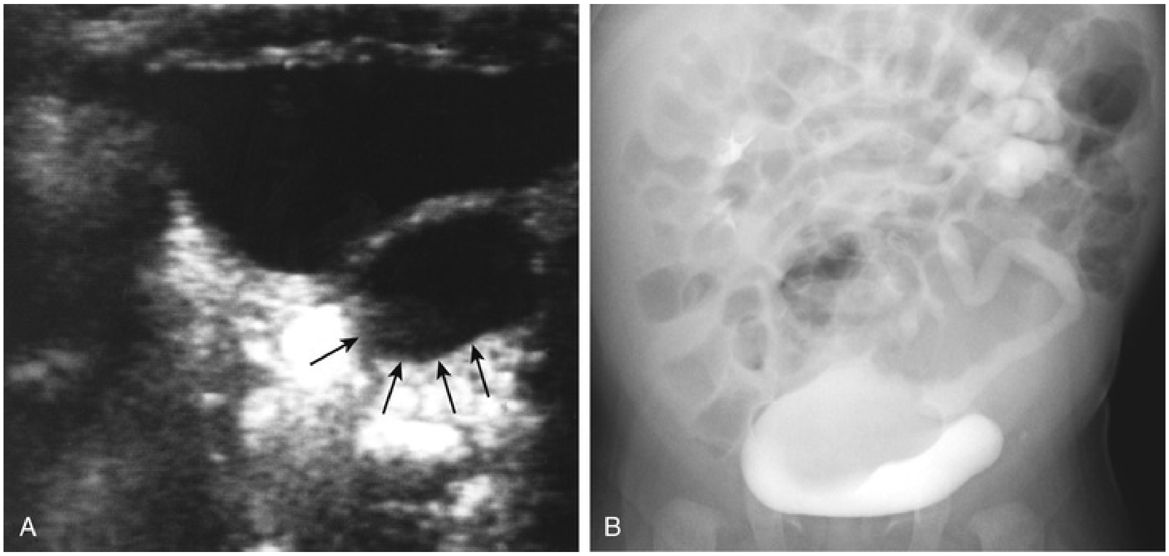

FIG. 41.12 (A) Ultrasound image of a bladder in a child with an ectopic ureter extending into the bladder. The wall of the ureter is thicker than the ureterocele, and the lumen of the ureter extends well outside the bladder lumen, indicating that this is an ectopic ureter rather than a ureterocele. (B) Voiding cystourethrogram of a large ectopic ureter pushing inward on the back of the bladder and appearing as a filling defect in the bladder (pseudoureterocele). (B, Courtesy of Dr. Jeanne Chow, Assistant Professor of Radiology, Harvard Medical School and Children's Hospital, Boston.)

Voiding Cystourethrogram

The voiding cystourethrogram (VCUG) provides the most definitive evaluation of the bladder and urethra and often of the distal ureters and is an obligatory imaging test. This should almost always be obtained before any intervention to define the baseline situation. The unusual situation in which a VCUG may not be obtained would be if decompression of a ureterocele producing bladder outlet obstruction or severe bilateral upper tract obstruction in an infant is urgently indicated. It is unlikely that the findings on VCUG would alter treatment, which would nearly always be transurethral puncture. The presence of reflux may determine initial treatment for some practitioners and is an important parameter in clinical management after initial decompression of the ureterocele. In the setting of an ectopic ureter, ipsilateral lower pole reflux is unlikely to resolve spontaneously and will influence definitive treatment options.

After incision of a ureterocele, the presence of reflux either ipsilaterally or contralaterally will be critical in therapeutic decision making.

Magnetic Resonance Imaging

Magnetic resonance urography can provide the most detailed images of an affected urinary tract, however magnetic resonance imaging (MRI) in young children often requires sedation and typically does not add information not already obtained with less expensive methods. At the present time, the value of MRI rests with patients in whom other imaging cannot define complex anatomy. This may occur in duplicated collecting systems with a nondilated upper pole, one with massive dilation in which the existence of duplication may be uncertain, or one in which anatomic relationships are significantly distorted (Fig. 41.13). If this type of anatomic delineation is needed, MRI offers the addition of functional information that is an important aspect of evaluation (Fig. 41.14).

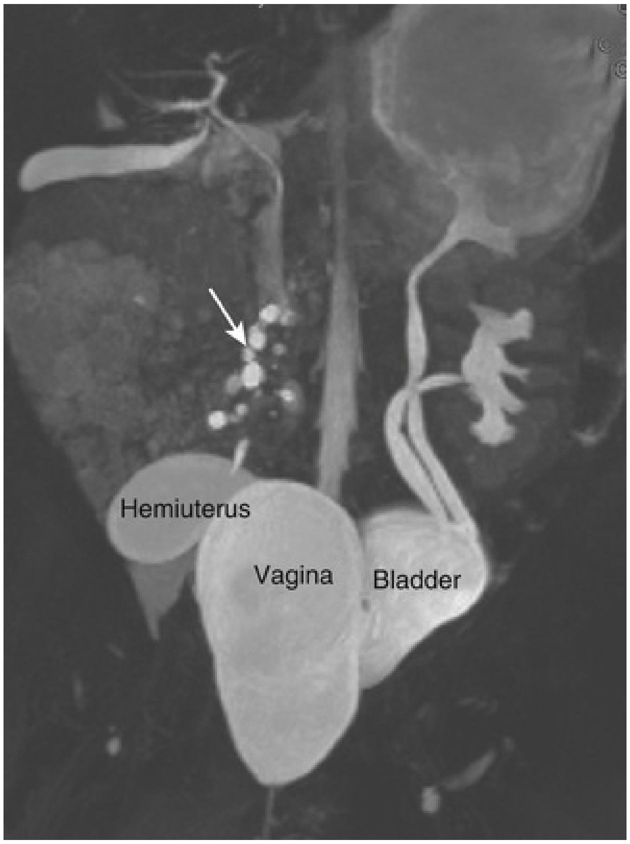

FIG. 41.13 Magnetic resonance image demonstrating the complex anatomy of a child with an ectopic ureter associated with a right dysplastic, cystic kidney *(arrow)* draining into an obstructed hemivagina and producing urinary dilation of the right hemiuterus. Initial therapy constituted creating a distal window between the two vaginae. Subsequently, the patient underwent right nephrectomy.

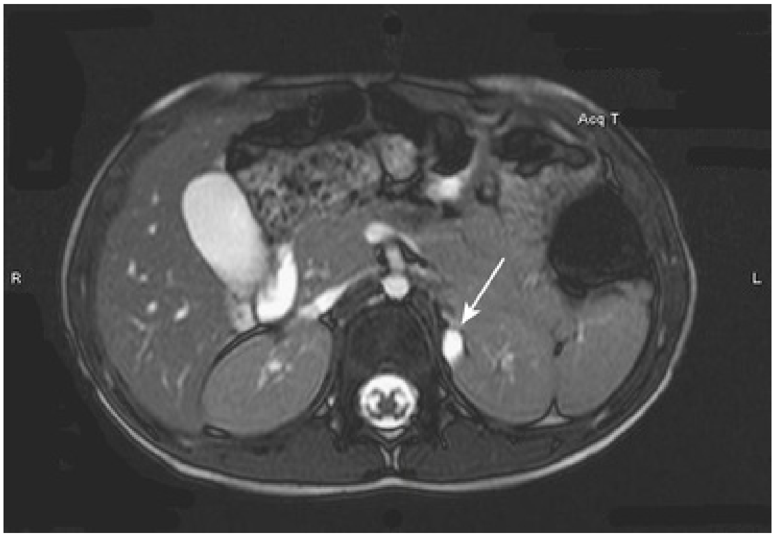

FIG. 41.14 Magnetic resonance urogram demonstrating the presence of an occult upper pole associated with an ectopic ureter producing incontinence. The left upper pole ureter is marked by the *arrow* at the level of the lower pole pelvis.

Functional Assessment

Functional urinary assessment in association with an ectopic ureter or ureterocele is the foundation for both initial management and postoperative care. Both renal and bladder function are affected by the developmental abnormalities of ureteral formation and may ultimately require complex surgical interventions.

Renal Function

Nuclear Imaging.

Radionuclide renal imaging remains the gold standard for renal functional assessment, and this is usually best afforded by dimercaptosuccinic acid (DMSA) imaging (Fig. 41.15A and B). The function of the affected upper pole is the principal focus, but the health of the other renal moieties must be determined as well, particularly if there is lower pole reflux or hydronephrosis of any unit. Although there have been some attempts to define what the “normal” function of an upper pole associated with an ectopic ureter or ureterocele should be, there are no criteria to define this. The clinical impact comes with the decision to preserve the upper tract or not, yet there are no objective parameters to determine what level of functional contribution should be preserved. The functional assessment therefore offers the dichotomy of some function versus no function, and this may or may not determine clinical management (see later). In general, this is clear, but there will always be ambiguous cases. Preoperative assessment is further complicated by the lack of ability to predict the effect of decompression.

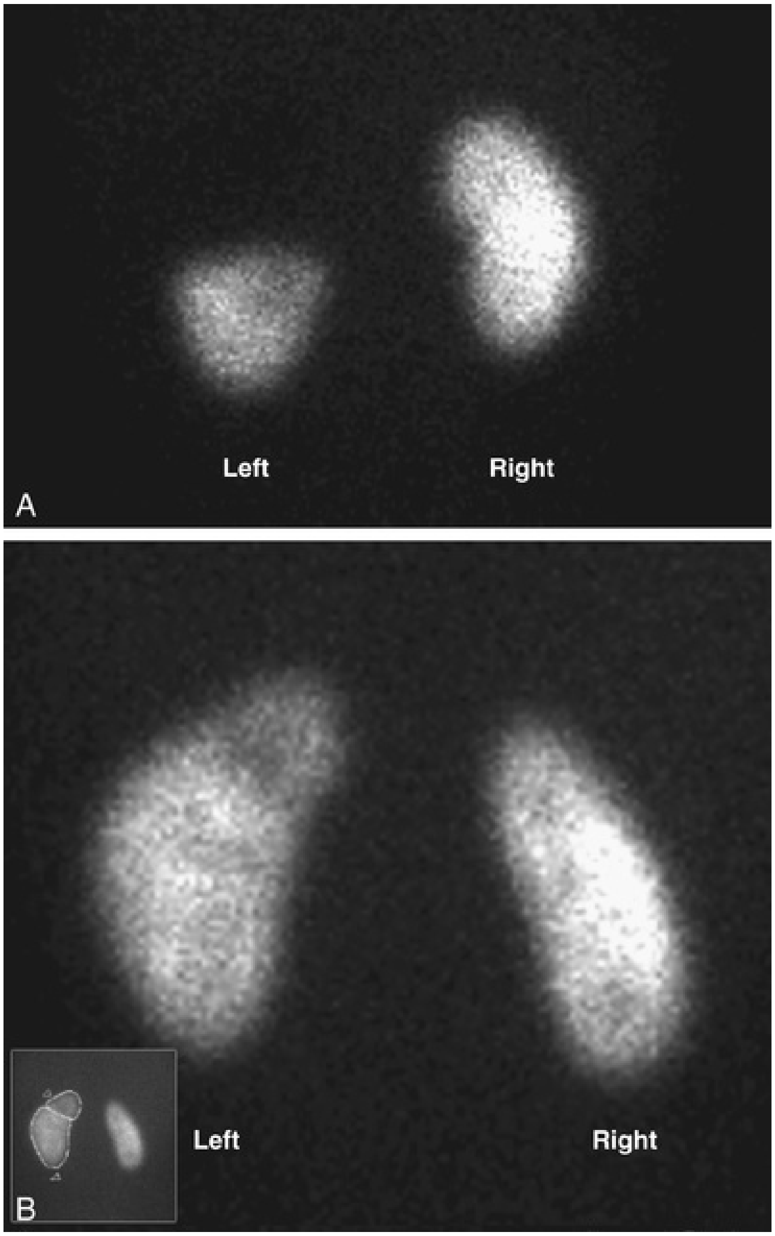

FIG. 41.15 (A) Dimercaptosuccinic acid renal scan in a child with a left ureterocele demonstrating no function in the affected upper pole. (B) Dimercaptosuccinic acid renal scan in a child with a ureterocele with evidence of upper pole function after transurethral incision to decompress the ureterocele. The upper pole was separately assessed as contributing

approximately 18% of total renal function.

The assessment of ureteroceles in which an observational approach may be considered is best accomplished with a diuretic renal scan (Han et al., 2005), which would then replace the DMSA scan. This provides both functional and drainage measurements. This has been shown to be of some clinical value in ureteroceles in which drainage is adequate, and ultimate resolution of the hydronephrosis has been reported (Han et al., 2005). A dilated ectopic ureter is only rarely suitable for observational management, so the value of an assessment of obstruction is limited.

Intravenous Pyelogram.

In unusual situations, the intravenous pyelogram (IVP) may offer adequate functional information with anatomic delineation without the complexities of an MRI. Functional assessment is only qualitative, however, and the IVP is a less useful baseline study except when the anatomy is uncertain or there is uncertainty about an ectopic ureter with no dilation in the setting of incontinence (Fig. 41.16).

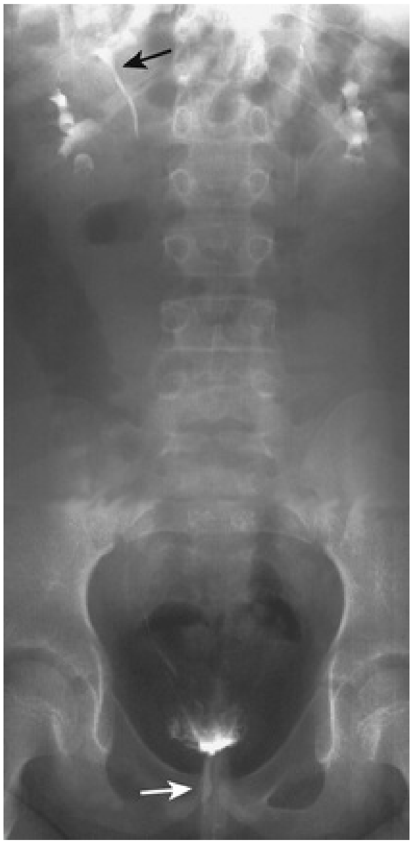

FIG. 41.16 Intravenous pyelogram in a 10-year-old child with lifelong wetting and evidence of ureteral duplication *(black arrow—upper pole)* with no hydronephrosis. The distal ureter *(white arrow)* can be seen passing by the bladder and bladder neck and inserting into the urethra near the perineum.

Bladder Function

Although the bladder is not the principal focus of clinical attention in the evaluation of the ectopic ureter or ureterocele, the potential for impaired bladder function cannot be ignored. This may be caused by bladder outlet obstruction from a ureterocele, or impaired continence resulting from inadequate bladder neck function with an ectopic ureter or ureterocele. In the extreme case of bilateral single-system ectopic ureters, bladder development may be severely impaired because of the absence of fetal bladder filling.

Ultrasound Imaging Interpretation

A simple bladder ultrasound image may be very useful in completing the functional evaluation of these patients. Waiting for bladder filling and emptying may yield information on bladder emptying efficiency and bladder wall thickness (indicative of possible outlet obstruction). The character, location, and size of the ureterocele can usually be assessed as well (see Fig. 41.11). In some cases, the ectopic nature of a dilated ureter may be identified ultrasonographically.

Ureterocele and Bladder Outlet

The appearance of the bladder base with filling and voiding demonstrated on VCUG (Fig. 41.17) is also useful in therapeutic decision making, because significant eversion indicates a weak trigonal floor that may be more likely to require surgical repair. Prolapse of a ureterocele into the urethra or demonstration of a cecoureterocele is an important factor in planning and performing a TUI and may be more predictive of the subsequent need for secondary surgery. **The usual descriptive terms in the context of a ureterocele include *prolapse,* which is movement of the ureterocele into the urethra, eversion, or diverticulum-like protrusion of the bladder base and trigone with filling and voiding (Fig. 41.18), and *intussusception,* or protrusion of the ureterocele back into its ureter (Fig. 41.19).**

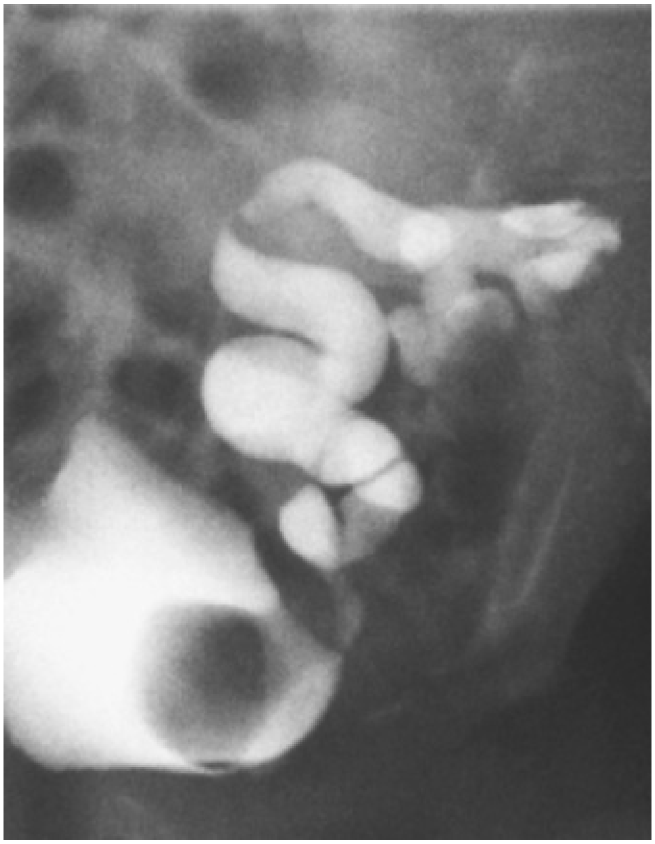

FIG. 41.17 Voiding cystourethrogram in a child with a ureterocele appearing as a filling defect within the bladder and massive ipsilateral lower pole reflux.

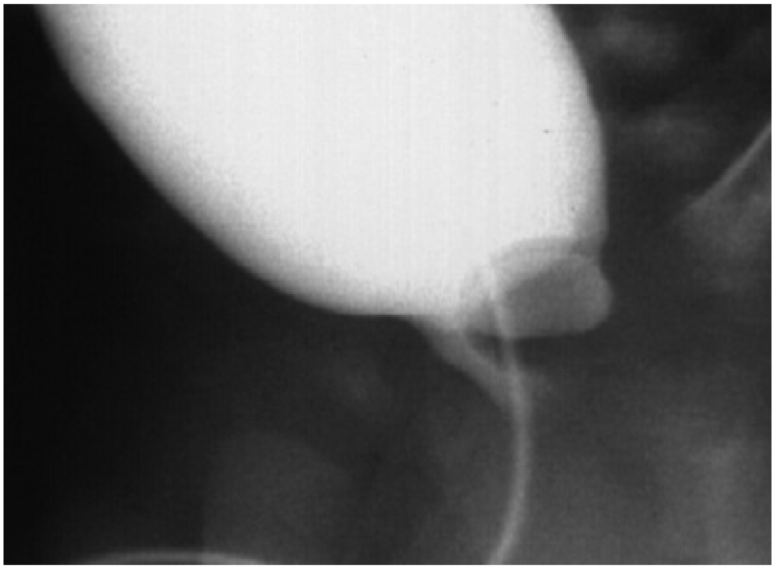

FIG. 41.18 Voiding cystourethrogram in a child with ureterocele and evidence of prolapse of the ureterocele into the bladder neck with voiding.

This is distinct from a cecoureterocele, in which the ureterocele is part of the urethra. This pattern of prolapse can cause bladder outlet obstruction.

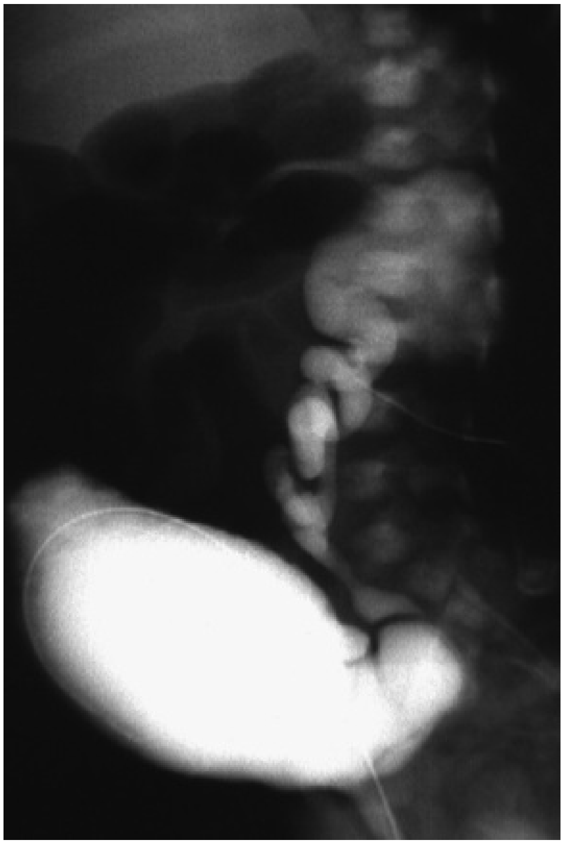

FIG. 41.19 Voiding cystourethrogram in a child with a ureterocele and evidence of ureterocele eversion with voiding. The apparent diverticulum is the ureterocele extending outside the bladder wall with increased intravesical pressure. This pattern may be seen with the ureterocele everting or intussuscepting into its dilated ureter. There is lower pole reflux as well.

Although it is difficult to predict continence at initial presentation, the ureterocele or ectopic ureter associated with a patulous bladder neck may be complicated by later urinary incontinence. Cecoureteroceles are a particular risk factor for incontinence, but we have also observed bladder neck ectopic ureters with wide-open bladder necks and later incontinence after resection of the distal ectopic ureter and external bladder neck reinforcement (Fig. 41.20). These patients may benefit from more aggressive bladder neck tightening at the time of definitive resection of the ureterocele or ectopic ureter; however, this entails some risk for disturbing what may be normal bladder neck function. Videourodynamic evaluation may be helpful in such patients.

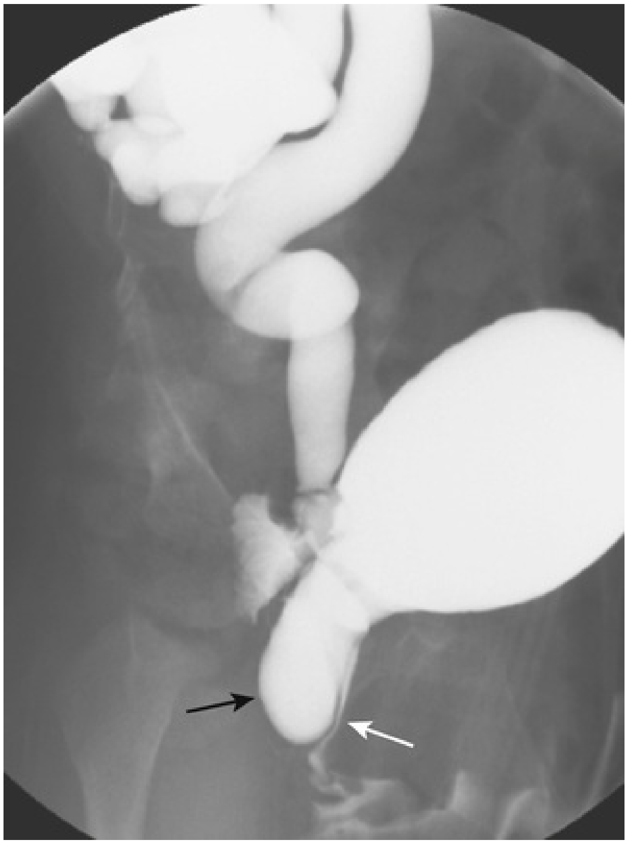

FIG. 41.20 Voiding cystourethrogram of a cecoureterocele in which the ureterocele *(black arrow)* is attached to the urethra *(white arrow)* and the lumen extends into the urethra. These are the most challenging ureteroceles because there is involvement of the bladder neck and urethra.

Endoscopic Evaluation

The final element of evaluation of a ureterocele or ectopic ureter can be endoscopic. Although this is not always essential, most cases of both ureterocele and ectopic ureter will come to operative intervention, and concurrent endoscopic evaluation is important if not essential. Certainly when endoscopic incision is to be performed, this is a critical element and should be performed thoroughly before incision to permit selection of the most effective site.

Endoscopy should take note of the character of the urethra, bladder neck, and trigone relative to the ureterocele or ectopic ureter. The location of the other ureteral orifices should be documented. The orifice of the affected

ureter should be sought but may not be identified. The urethra is examined carefully for the orifice if not seen in the bladder. **The appearance of the ureterocele will vary with bladder filling, and it is best to start with little filling and slowly increase bladder volume (Fig. 41.21).** The ureterocele will be seen to slowly flatten. Its true limits are best appreciated with limited bladder filling; this will expose the lowest portion, which is probably the best site for incision. Extension of the ureterocele into the urethra, indicative of a cecoureterocele, may be detected, and this indicates the need to make sure this section does not cause obstruction with incision. Retrograde contrast injection can confirm the presence of ureterocele disproportion, as there will be only a narrow proximal ureter and no filling of an upper pole segment (see Fig. 41.5). Unusual connections with the genital ducts may also be demonstrated as in the example of a boy with a ureterocele and communication among the ureter, vas deferens, and seminal vesicles (see Fig. 41.2).

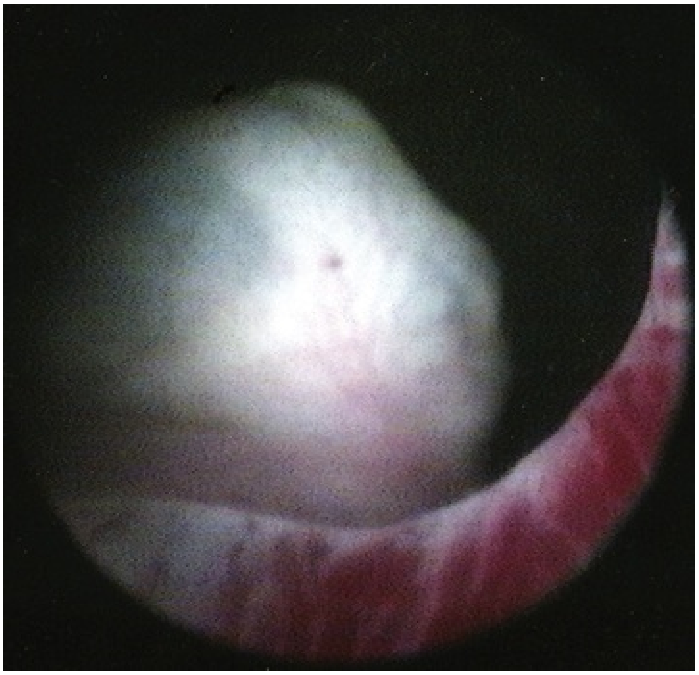

FIG. 41.21 Endoscopic image of an intravesical ureterocele just inside the bladder neck.

An ectopic ureteral orifice may be very difficult to find endoscopically, but if it is in the bladder neck, it is often patulous (Fig. 41.22). The anatomic connections of the ectopic ureter may be demonstrated using retrograde contrast studies. We have identified ectopic ureters that appear to have a very thin layer of tissue separating them from the urethra, looking much more like a ureterocele than an ectopic ureter (Fig. 41.23A and B). These may be associated with defects in the bladder neck and incontinence (see Fig. 41.23C). Consideration for more extensive removal of these patulous segments with reconstruction of the bladder neck may be part of the clinical decision, and their endoscopic appearance can facilitate this decision.

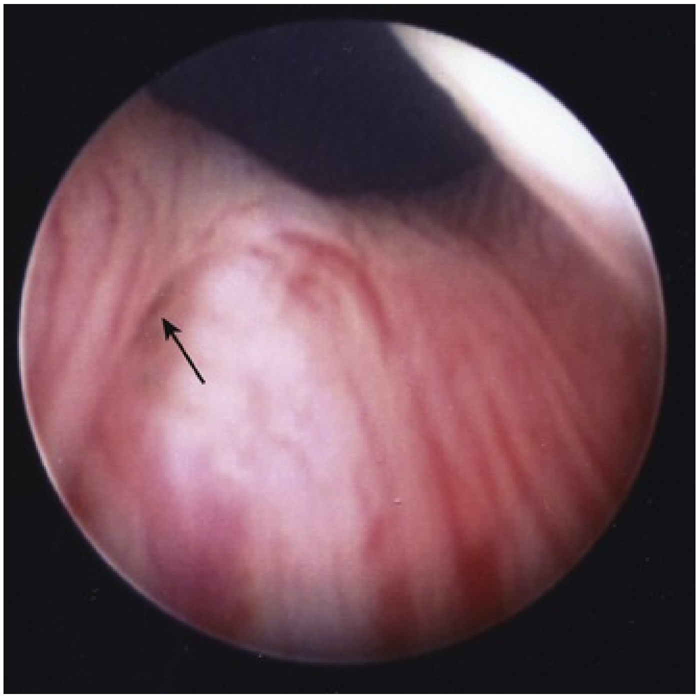

FIG. 41.22 Endoscopic images of a bladder neck and ectopic ureteral orifice *(arrow).* Bladder neck ectopic ureteral orifices are often patulous but do not always reflux.

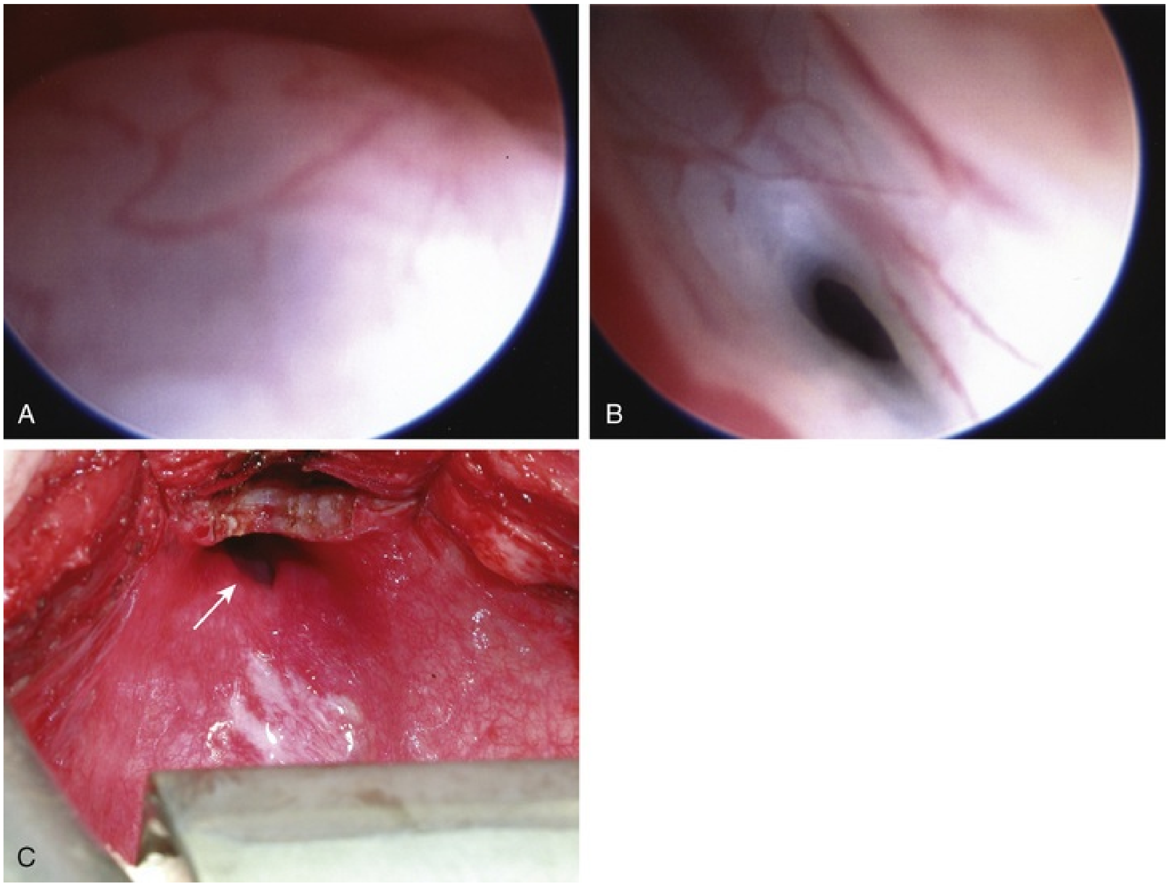

FIG. 41.23 (A, B) Endoscopic images of bladder neck orifices of an ectopic ureter with an appearance similar to that of a ureterocele without the dilated intravesical portion. The membrane overlying the orifice was thin and fluttered with irrigation, just as a ureterocele would be. (C) At open surgery, these bladder neck ectopic ureters can have the appearance of a defect in the bladder neck *(arrow)* and be associated with incontinence. It remains unclear how these ectopic ureters are related to ureteroceles.

Key Points: Evaluation of Ectopic Ureters and Ureteroceles

- An ultrasound image usually provides the anatomic diagnosis of an ectopic ureter or ureterocele and permits an inference of renal function.
- Typical findings are of hydroureteronephrosis in a single system or of a dilated upper pole with ureteral dilation in a duplicated system.
- The ureterocele is characterized by a thin-walled, cystic dilation within the bladder and not extending beyond its walls.

- A very dilated ectopic ureter may produce an impression on the bladder and appear as a ureterocele; this is called a *pseudoureterocele*.
- Radionuclide renal imaging remains the gold standard for renal functional assessment, and this is usually best provided by DMSA imaging. A mercapto-acetyl-triglycine (MAG3) renal function study with Lasix can be considered when need to determine both renal function and degree of obstruction.
- The function of the affected upper pole is the principal focus, but the health of the other renal moieties must be determined as well.
- VCUG provides the most definitive evaluation of the bladder and urethra.
- The appearance of the bladder base with filling and voiding demonstrated on VCUG will also be useful in therapeutic decision making, as massive eversion indicates a weak trigonal floor that may be more likely to require surgical repair.
- Endoscopy should take note of the character of the urethra, bladder neck, and trigone relative to the ureterocele or ectopic ureter.

Clinical Management

Management Goals

It should again be stressed that, before any surgical intervention for ectopic ureters or ureteroceles, the surgeon must obtain as much information as possible regarding the patient's altered anatomy and its potential clinical impact. Only then can a rational treatment plan be devised. Although specific and definitive management for ectopic ureters and ureteroceles differ, the goals of management are the same, and in many cases the approaches are identical.

The goals of therapy should be clearly defined and factored into the clinical decisions. These goals are preservation of renal function; elimination of infection, obstruction, and reflux; and maintenance of urinary continence. Minimizing surgical morbidity is a goal that must be included in this consideration. Although the goals of treatment are generally agreed upon, the means to achieving these goals remain controversial. One area in which there is some general agreement is that early institution of a daily prophylactic antibiotic can reduce the risk for UTIs in patients in whom there is significant hydronephrosis.

Historical Perspective

Initial management for ureterocele and ectopic ureter focused on the same goals as today, and ureterocele excision using open surgery was described in the early 1950s (Gross and Clatworthy 1950; Campbell, 1951). Total reconstruction with removal of nonfunctioning renal tissue and reconstruction at the level of the bladder with ureterocele excision and/or reimplantation was presented as a viable option in the mid-1950s and again became popular in the 1970s with the reports of Hendren et al. and Kroovland et al. (Hendren and Monfort, 1971; Kroovand and Perlmutter, 1979). The upper tract approach for ureteroceles, with upper pole partial nephrectomy to decompress the ureterocele, became the standard approach in the 1980s (King et al., 1983). Endoscopic incision of the ureterocele, initially as a salvage approach in the septic child, gained widespread favor in the 1990s, but its use is now more selectively applied based on imaging criteria in the acute setting and a means of relieving obstruction and preserving renal parenchyma (Tank, 1986; Rich et al., 1990). Observational management has emerged more recently, although this remains controversial and is likely best used in cases of small ureteroceles with minimal hydronephrosis.

Ectopic ureter was usually managed surgically in nearly all patients. An early description of the clinical presentation and management of the ectopic ureter focused on removal of the associated renal unit in patients with incontinence (Alldred and Higgins, 1951). Presentation in most cases was relatively late, and residual renal function was usually limited. Excision was commonly the best option. With prenatal detection, salvage of the affected renal moiety has become a common option, usually with an upper to lower drainage procedure in duplicated systems.

Fetal Management

Widespread use of fetal ultrasonography has resulted in a large portion of ectopic ureters and ureteroceles being diagnosed prenatally. Duplicated systems without hydronephrosis may not be noted prenatally, but when hydronephrosis is present, this is usually easily noted prenatally. There is no role for fetal intervention in the ectopic ureter, however its identification can help plan postnatal management. If there is suspicion of ectopic ureter (or ureterocele) prenatally, a postnatal ultrasound should be obtained and a VCUG considered. A recommendation for prophylactic antibiotics to be started at birth is often made to limit the risk for early UTI. Subsequent workup and management can be determined based on these initial studies. Ureteroceles are also not typically an indication for fetal intervention except in the rare instance when the ureterocele is large and causes obstruction of all renal units. In these patients, cystoscopic laser ablation of the fetal ureterocele has emerged as a management technique, although the procedure is still considered experimental and is only performed in select centers (Chalouhi et al., 2017; Persico et al., 2017).

Neonatal Management

Nonurgent Management

Most ureterocele and ectopic ureter patients are seen in a nonurgent manner, either in consultation after a baby with such an abnormality is born or in the clinic as a neonate. Evaluation should always start with renal ultrasonography. If there is significant hydroureteronephrosis caused either by a ureterocele or ectopic ureter, the start of prophylactic antibiotics should be considered and a

VCUG ordered. The determination for continuation or prophylactic antibiotics can be made thereafter. Even in the absence of reflux, prophylaxis can be considered to minimize the risk for infection in the setting of hydroureteronephrosis with obstruction. A renal function study is often obtained when the child is old enough for the study (generally older than 2 months of age) to assess the degree of renal function in the obstructed segment and other moieties.

In the case of the small ureterocele with minimal degree of hydronephrosis and no or little demonstrable obstruction, observation is one management option. In cases of significant hydronephrosis with obstruction, especially if the parenchyma in the obstructed segment is compromised, consideration should be given to proceeding with TUI. Various methods for puncture have been described. The most commonly used method is a low transverse incision, but a "watering can" technique to the incision of the ureterocele has also been described, in which a holmium laser is used to puncture multiple holes in the ureterocele in the hopes that the risk for *de novo* VUR will be lower than with traditional incision (Haddad et al., 2017). If an endoscopic approach cannot be undertaken, a cutaneous distal ureterostomy can be performed to divert the urine until the child is old enough for formal reimplantation.

Urgent Management

In the child who presents with sepsis of urinary origin in the setting of obstruction caused by an ectopic ureter or ureterocele, antibiotics are usually sufficient to clinically stabilize the patient, however if the child does not respond promptly and appropriately, a TUI of an obstructing ureterocele or a nephrostomy tube drainage of the ectopic ureter should be considered. A cutaneous distal ureterostomy can also be performed in either setting to promptly and reliably establish drainage. Once the child has proven to be prone to infection by presenting in this manner, a drainage procedure should be undertaken in a nonurgent fashion once the child is stabilized (if such a procedure was not required urgently) to prevent future infections.

General Management Principles

For both ectopic ureter and ureterocele associated with a duplicated system, a principle concern is the preservation of functional renal parenchyma. This goal is achieved by correcting obstruction and preventing reflux with its

risk for renal parenchymal damage from infection (Churchill et al., 1992). At times it is necessary to balance one against the other, because relieving the obstruction of an ectopic ureter or ureterocele may induce reflux in either or both poles of the involved kidney. In other instances, the same action may cause existing lower pole reflux to resolve. Several methods of achieving these goals are available. The decision making regarding when and how to intervene is quite subjective however, and decisions regarding how much renal function is worth preserving should be made on an individual basis. **For an ectopic ureter, this can mean ureteral reimplantation or, in case of a duplex kidney, common sheath reimplantation or ureteroureterostomy, either low or proximal near the renal pelvis.**

A recently described technique for management of the ectopic ureter in the young child who is not yet old enough for a formal ureteral reimplantation is to create a side-to-side nondismembered refluxing anastomosis. Alyami et al. described using this technique to manage 29 patients with an average age at the time of surgery of 3.7 months. This group has performed this technique with the intention of considering it definitive in a certain population with a low risk for development of UTI. Long-term data will be necessary to determine the safety of this management technique and to determine how many children do, in fact, require further procedures (Alyami et al., 2017). For a ureterocele, this can be accomplished with TUI as well as ureterocele excision and common sheath reimplantation or ureteroureterostomy. In both cases, acute decompression may be necessary because of sepsis and the age of the child. For the ectopic ureter, acute decompression is best achieved with an end ureterostomy near the bladder, whereas for a ureterocele, TUI is usually effective.

The decision making for renal parenchymal preservation is largely empirical, and there are few objective criteria to indicate how much residual function is worth preserving. The presence of VUR into either of the ureters must be considered as well, and every effort should be made to correct this with the drainage procedure.

Ectopic ureters and ureteroceles are overwhelmingly dealt with postnatally. Although one might reason that a prenatal diagnosis could lead to earlier relief of obstruction and presumably a greater chance of recovery of upper pole function, the evidence in the literature seems to show that there is a limited recovery of function, even with early decompression. The observations by Tank using early endoscopic puncture demonstrated function that had not been detected before drainage (Tank, 1986). Impaired function of the upper pole occurs equally in those diagnosed prenatally and postnatally (Upadhyay et al., 2002). In most instances, the upper pole contributes little to overall renal function, but as discussed earlier, there are no criteria for what should be normal upper pole function.

Key Points: Clinical Management—Goals of Treatment

- The goals of therapy are preservation of renal function; elimination of infection, obstruction, and reflux; and maintenance of urinary continence.
- Minimization of overall procedural morbidity is also a goal of treatment.
- For both ectopic ureter and ureterocele associated with a duplicated system, a primary concern is preservation of functional renal parenchyma.
- Decision making for renal parenchymal preservation is largely empirical, and there are few objective criteria to indicate how much residual function is worth preserving.
- For an ectopic ureter, this can mean common sheath reimplantation or ureteroureterostomy, either low or proximal near the renal pelvis.
- For a ureterocele, this can be accomplished by TUI, as well as ureterocele excision and common sheath reimplantation or ureteroureterostomy.
- Observational management of ureteroceles in carefully selected patients is a reasonable option, with the potential for spontaneous decompression.

Observational Management

Several groups have reported nonoperative management of ureteroceles meeting criteria of no obstruction of the ipsilateral lower pole or contralateral kidney and limited reflux to the lower pole (grade III or less) (Shankar et al., 2001; Direnna and Leonard, 2006), no function of the upper pole, or no obstruction on diuretic renography (Han et al., 2005). Coplen and Austin described a subset of patients with ureteroceles and multicystic dysplastic kidneys in the associated upper tract segment (Coplen and Austin, 2004). This group had either low-grade or no reflux and no ureteral dilation. These prenatally diagnosed patients were managed nonoperatively and had a benign clinical course. Clearly some children will do well for a period without intervention, and in some patients resolution of upper pole dilation and lower pole reflux has been reported. It is challenging to know how to counsel families regarding this approach, as the potential for later, unpredictable acute presentation is real. For that individual, even if with a low statistical incidence, it is very significant clinically. The long-term risk and relative balance of morbidities of this strategy and the robustness of clinical predictors have yet to be determined. Carefully considered, observational management of children with ureteroceles can be an appropriate strategy with careful selection and parental education.

Total Reconstruction

Total reconstruction of both upper and lower tracts has been advocated by some authors as being the most definitive procedure for ureteroceles (Hendren and Mitchell, 1979; Kroovand and Perlmutter, 1979). **Upper pole heminephrectomy with ureterocele excision and reimplantation of the lower pole ureter is definitive but is an extensive operation performed with two incisions.** Although the reported success rates are good, it remains uncertain if this is appropriate in most children when long-term relief from obstruction and reflux may be achieved with one or at most two lesser procedures. The older child with a massive ureterocele and no function of an upper pole with significant lower pole reflux might be reasonably treated with upper pole nephrectomy and ureterocele excision and bladder reconstruction. At the present time, the partial nephrectomy would be reasonably performed laparoscopically or retroperitoneoscopically with a lower Pfannenstiel incision for the bladder reconstruction and reimplantation.

Upper Pole Partial Nephrectomy

Upper pole removal using a partial nephrectomy or heminephrectomy of a duplex system has long been viewed as the preferred treatment when there is clearly no function in the upper pole and if there is concern about how effective a drainage procedure may be because of massive dilation. There are numerous series advocating one or another approach, with variable results dependent on factors such as degree of reflux, age, and underlying pathology, but there are no clear data to indicate that one approach is so definitively better as to be the universal choice.

The surgical methods for partial nephrectomy have been described and remain useful and similar whether being used with open surgery, conventional laparoscopy, or robotic laparoscopy. The techniques are applicable to both ectopic ureters and ureteroceles in duplex systems.

Open Partial Nephrectomy or Heminephrectomy

Heminephrectomy is a standardized procedure with relatively little recent evolution (Mor et al., 1994), but several technical points deserve emphasis (Fig. 41.24). A flank approach for heminephrectomy usually offers better exposure to the upper pole vessels. The procedure may be performed through a dorsal lumbotomy approach, which is both effective and less morbid than a muscle-dividing flank incision. In older children, this exposure can be more challenging, however.

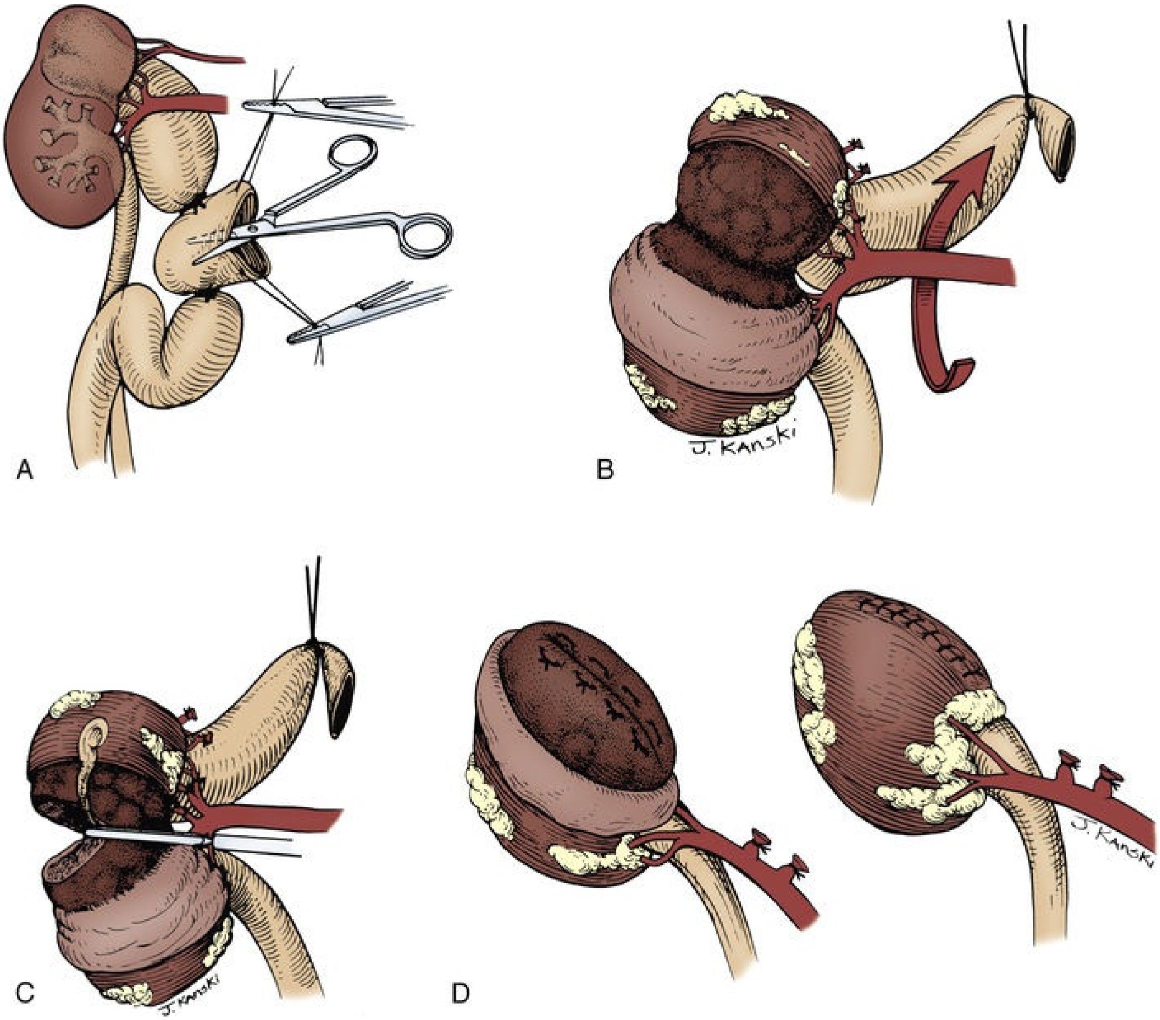

FIG. 41.24 Technique of upper pole nephrectomy. (A) The upper pole ureter is usually dilated and tortuous and can be identified readily at the

lower pole of the kidney. It is separated carefully from the lower pole ureter, divided, and used to improve access to the upper pole moiety. (B) The upper pole ureter is passed beneath the hilar renal vessels and retracted upward. Small feeding vessels to the upper pole are individually ligated and divided. Any larger vessels that may be supplying the upper pole can be temporarily clamped to determine the extent of their distribution. The capsule of the upper pole is bluntly stripped away, exposing the often coarse and cystic parenchyma of the upper pole. This can usually be distinguished from the smooth texture of the normal lower pole. Often, an indented demarcation is seen between the two poles. (C) While traction is applied to the lower pole ureter, the upper pole is excised with the use of electrocautery. Vascular control is achieved by temporary clamping of the lower pole vessels. This may also be accomplished by gentle finger compression of the lower pole. Individual vessels are identified and ligated during this part of the procedure. (D) The parenchyma of the lower pole is approximated at the site of removal of the upper pole with the use of broad mattress sutures. The redundant capsule is then brought over the site of repair and sewn together with a running suture.

In an upper pole nephrectomy, the primary concern is to avoid damaging the viable lower pole. The kidney should be retracted gently so as not to cause any vascular injury through traction and spasm of small vessels. Transecting the upper pole ureter and placing a traction stitch on the proximal portion of this ureter affords the surgeon a good method of retraction and manipulation of the upper pole. Once at the pedicle, dissection of the ureter both below and above the vessels allows for easier, safer freeing of the ureter. The ureter is passed behind the main renal vessels. The dissection *around* the renal vessels should be done carefully to avoid damage to the lower pole. The upper pole vessels (most often two or three in number) are sequentially ligated. Demarcation of the upper pole parenchyma becomes apparent after the upper pole vessels are ligated.

During upper pole nephrectomy, atraumatic clamping of the renal pedicle can be used, enabling work in a bloodless field. Administration of an intravenous osmotic diuretic (e.g., mannitol) moments before and after clamping of the pedicle helps prevent acute tubular necrosis. Topical vasodilating agents (e.g., papaverine) should be available in case vasospasm occurs. In general, vascular control is not essential in upper pole partial nephrectomy because the polar vessels can be identified and controlled. Resection of the upper pole renal tissue can then be carried out with electrocautery or another cutting device. Stripping the capsule off the upper pole in continuity allows it to be used in the closure. Several mattress sutures incorporating a pedicle of retroperitoneal fat are used for closure.

When performing the upper pole ureterectomy, it is of utmost importance to maintain the dissection immediately on the wall of the upper pole ureter as much as possible to preserve the blood supply to the remaining lower pole ureter.

If in addition to obstruction there is concomitant reflux into the ectopic ureter, some recommend a second incision (i.e., a Gibson incision) to resect the ureter in its entirety. Care must be taken to avoid injury to the vas deferens in male patients. To prevent complications that may arise from dissection within a common sheath of two ureters (especially distally), the back wall of the upper pole ureter can be left attached to the lower pole ureter. The remainder of the upper pole ureter should be removed (Fig. 41.25A to C). Such a maneuver prevents damage to the lower pole ureteral blood supply, which courses between both ureters. Resection is carried out to the level of the bladder, where several sutures are placed to close the upper pole ureteral hiatus.

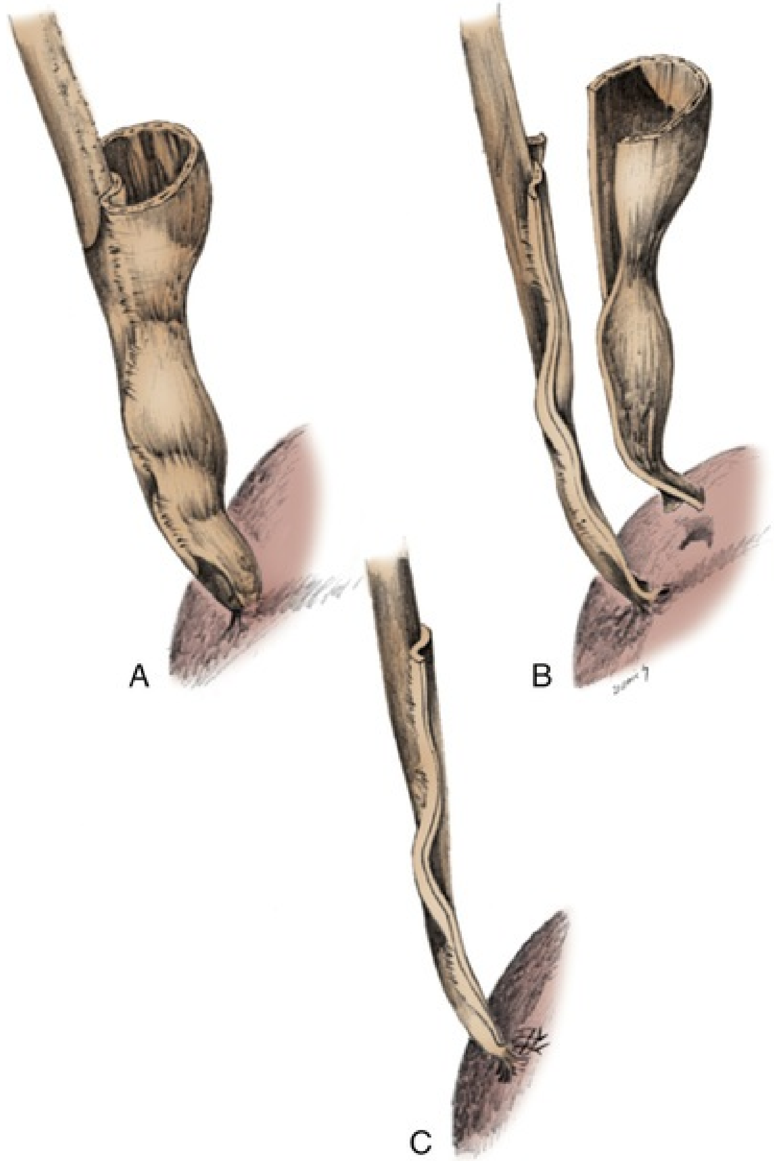

FIG. 41.25 Surgical management of the refluxing ureteral stump. (A) It is difficult to completely separate the distal 2 to 3 cm of the upper pole ureter from the lower pole ureter. The ectopic ureter is excised to this point. (B) The outer wall of the ectopic ureter is excised to the bladder level. (C) A transfixing suture obliterates its lumen, with care taken not to injure the orthotopic ureter.

Other surgeons are comfortable ligating the distal refluxing ureteral stump and leaving it in situ, with few subsequent problems attributed to the small volume of reflux into that stump (Cain et al., 1998; Kim et al., 2001). The refluxing, obstructed ectopic ureter raises the most concern regarding a later infection, and as much of the ureter should be removed as is possible without injury to the bladder neck.

A Penrose drain (brought through a separate counterincision or at the edge of the incision) is placed in such a fashion as to drain the renal fossa and the area of the ureteral dissection. **Postoperative evaluation is best performed with a Doppler sonogram to demonstrate normal postoperative anatomy, absence of a urinoma, and normal blood flow to the lower pole.** Optionally, a functional study such as a nuclear renal scan may be performed if there is concern regarding viability of the lower pole.

Laparoscopic and Robotic Partial Nephrectomy

Another surgical option is laparoscopic or robotic nephrectomy or heminephrectomy. This can be done by either a transabdominal or a retroperitoneal approach, with robotic assistance being increasingly common. These minimally invasive procedures may offer reduced morbidity with less postoperative pain, earlier return of gastrointestinal function, earlier discharge home, and presumably a quicker return to work for the parents (Jordan and Winslow, 1993; Janetschek et al., 1997; El-Ghoneimi et al. 1998b; Lee et al. 2005; Wallis et al., 2006; Lee et al., 2009; You et al., 2010). Other advantages include enhanced visualization and increased magnification of the operative field, improved cosmesis, and avoidance of a second incision that is often needed for the distal ureterectomy of a nephroureterectomy.

Laparoscopic heminephrectomy can be performed in very small infants, and the operative time has decreased as experience and skill have increased (El-Ghoneimi et al., 2003; Lee et al., 2005; Sydorak and Shaul, 2005; Piaggio et al., 2006). Newer energy devices allow for resection of the upper pole in a bloodless field (LigaSure, Valleylab, Boulder, CO; Harmonic scalpel, Ethicon EndoSurgery, Cincinnati, OH; Thunderbeat, Olympus, Tokyo, Japan; and Vessel Sealer, Intuitive Surgical, Sunnyvale, CA).

Laparoscopic heminephroureterectomy performed transperitoneally begins similarly to the open procedure in that the pathologic ureter is grasped as a handle and dissected closely to its wall to avoid compromise of the blood supply to the normal ureter. The upper pole ureter is passed behind the vessels and used to facilitate dissection of the upper pole. The polar renal vessels are then ligated with clips or divided with electrocautery; this allows for a more discernible demarcation of the affected upper pole (Fig. 41.26A). The plane between the upper pole collecting system and the upper parenchyma of the lower pole is developed bluntly to facilitate identifying and transecting the upper pole attachments to the lower pole (see Fig. 41.26B). After the polar element is removed with electrocautery or another energy source, one can check for collecting system leakage with intravenous injection of methylene blue (Yao and Poppas, 2000). Janetschek et al. placed fibrin glue and hemostatic agents on the cut surface and then covered it with Gerota fascia to aid in hemostasis (Janetschek et al., 1997). We have not used these agents but have closed the defect over a pedicle of local fatty tissue (see Fig. 41.26C). Closure of the defect may limit the incidence of postoperative fluid collections (Mason et al., 2014).

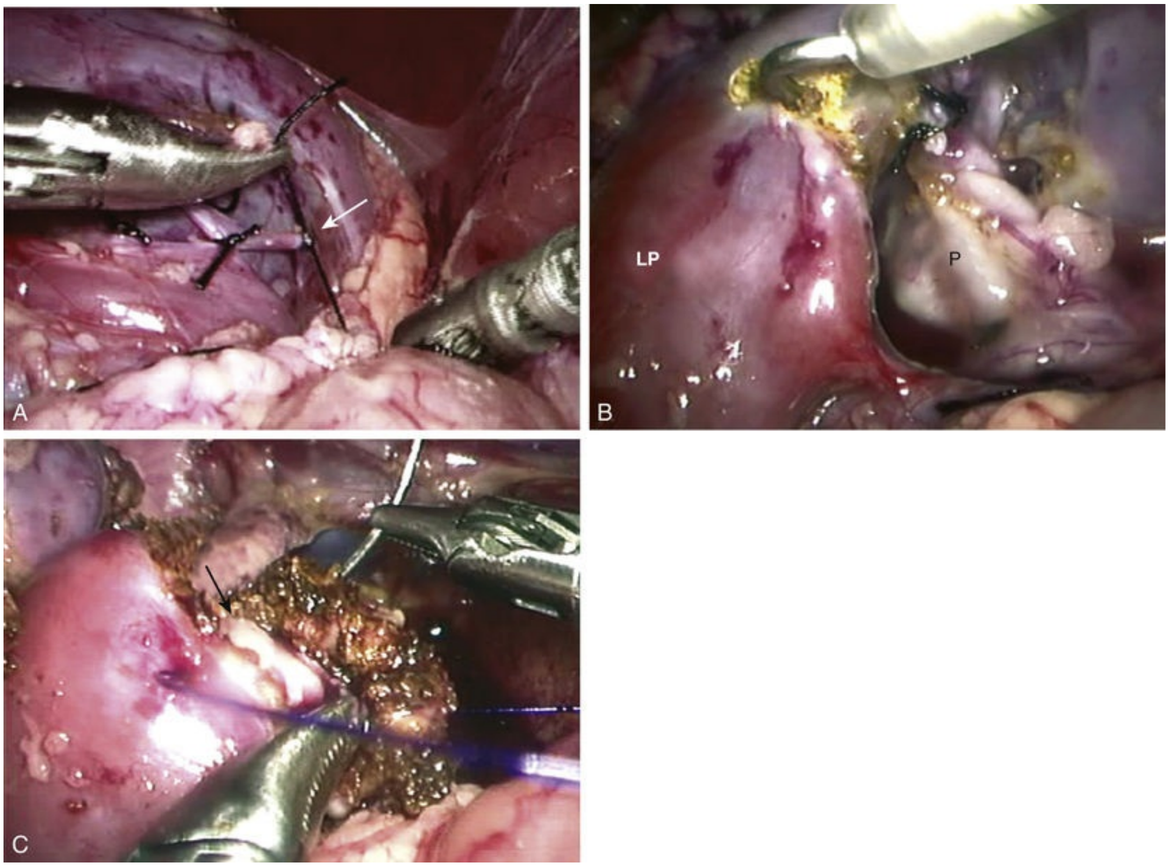

FIG. 41.26 Laparoscopic images of a robotic-assisted upper pole nephrectomy. (A) Isolation and ligation of the multiple vessels to the dilated upper pole *(white arrow).* In some cases, a single vessel is identified, but often these are multiple. (B) The thin dysplastic parenchyma of the upper pole and upper pole pelvis *(P)* is incised using cautery, separating it from the healthy lower pole *(LP).* (C) Mattress sutures are placed over a bolster of fat *(black arrow)* to close the defect in the upper portion of the lower pole.

In performing a partial nephrectomy, robotic-assisted laparoscopy offers advantages over standard laparoscopy (Lee et al., 2009). The magnification is augmented, and the dexterity of the robotic instruments allows for greater precision when working around the renal pedicle and controlling the upper pole vessels, in addition to the visual advantages of a three-dimensional image. Patient and port positioning are the same as for pyeloplasty. Vascular control may be by absorbable or metal clips or even with suture ties. The latter may be preferable by reducing the risk for avulsing a clip during later dissection. The defect is usually closed with a tongue of retroperitoneal fat laid into the defect, which is then closed with two or three mattress sutures of 3-0 polydioxanone suture (PDS) or Vicryl. The robotic approach to heminephrectomy has been described for both upper and lower pole heminephrectomy with successful outcomes (Wiestma et al., 2016).

Laparoendoscopic single-site surgery (LESS) nephrectomy has been described for a single-system ectopic ureter. This technique represents the newest horizon for minimally invasive surgery because only one 22-mm multitrocar port site (recessed in the umbilicus) is used to perform the entire surgical procedure (Park et al., 2009). Newer robotic technology utilizing a single-site platform offers the potential of the precise movement control of robotics with even less surgical morbidity. The current device is too large for smaller children, however.

Ureteral Clipping

A recently described technique for management of nonfunctioning or poorly functioning renal moieties associated with ectopic ureter or obstructive ureteroceles involves laparoscopic clipping of the involved ureter without extirpative surgery. The group encountered two complications in 35 patients including a patient who developed pyonephrosis necessitating nephrectomy and a patient with a duplex system who developed a febrile UTI and persistent upper pole hydronephrosis. The utilization of this technique is still in its infancy, and we advise that caution should be used. Long-term follow-up is unavailable, and these patients should be monitored long term for potential complications such as infection and hypertension (Romao et al., 2014; Lopes et al., 2018).

Laparoscopic vascular ligation of the poorly functioning upper pole vessels has also been reported as effective (Hosseini et al., 2017).

Outcomes

Results of upper pole removal for ectopic ureters and ureteroceles are, in general, very good. The residual stump is rarely problematic in cases of an

ectopic ureter. In cases of ureteroceles in which lower pole reflux is present, resolution may be expected in up to 20% (Husmann et al., 1999)**, and new reflux may be seen in 15% to 50% of patients in whom no reflux was present preoperatively.** The overall secondary surgery rate after primary upper pole nephrectomy for ureterocele is 40% to 50% based on the literature. The difficulty in interpreting the literature rests in variable indications for secondary surgery. In some cases, any presence of reflux postoperatively was considered an indication for further surgery at the level of the bladder, and in other cases reflux was monitored with intervention only in cases of clinical problems such as UTI. Neither of these approaches has been validated by long-term data.

Complications.

The most significant complication related to heminephrectomy is loss of lower pole function (Mandell et al., 1980; Wallis et al., 2006; You et al., 2010). Loss of function may be a long-term issue and may not be recognized immediately. Clinical signs that may suggest problems include fever, increasing pain, and hematuria and may be evident in the first week after surgery. **Development of a postoperative upper pole urinoma has been reported in up to 20% of laparoscopic and robotic cases but is rarely of clinical significance** (Valla et al., 2003; You et al., 2010; Mason et al., 2014). Urinomas have been reported mostly in series in which there is no formal closure of the polar defect. Whether these urinomas are caused by injury to the lower pole or remnant upper pole is unclear. Urinomas, if causing no symptoms and not expanding, can be observed. Other less common problems can include inferior vena cava laceration, duodenal perforation, need for total nephrectomy, and peritoneal tears (if the procedure is done retroperitoneally).

Key Points: Upper Pole Nephrectomy

- In an upper pole nephrectomy, the primary concern is to avoid damaging the viable lower pole.
- Separation of the duplicated ureters during intravesical dissection is discouraged because it can lead to injury of the common blood supply running longitudinally between the two ureters.
- Postoperative evaluation is best performed with Doppler sonography to

assess postoperative anatomy, identify a urinoma, and document normal blood flow to the lower pole.

- Definitive cure by partial nephrectomy for ectopic ureters is usually successful, as the residual stump is rarely problematic.
- For ureteroceles in which lower pole reflux is present, resolution of reflux may be expected in up to 20% of patients, and new reflux may be seen in 15% to 50% of patients in whom no reflux was present preoperatively.
- Complications related to heminephrectomy include loss of lower pole function and development of a postoperative upper pole urinoma.

Lower Tract Reconstruction

A definitive reconstruction at the bladder is suitable for both the ectopic ureter and ureterocele. This approach has the advantage of relieving obstruction and correcting reflux. The disadvantages, however, are the potential for injury to the bladder neck and vagina and the complexity of the procedure. If clinically significant reflux persists after other procedures, lower tract reconstruction may be necessary.

Ureterocele Excision and Common-Sheath Reimplantation

The intravesical approach to the ureterocele begins with a transverse incision of the ureterocele between two stay sutures (Figs. 41.27A to C and 41.28A). Proximally, a plane is obtained between the ureterocele wall and the wall of the bladder. The ureterocele is dissected off the bladder to the point at which it joins the lower pole ureter. Then the two ureters are dissected as a unit, the upper pole ureter is tapered as needed, and both ureters are reimplanted submucosally. The distal portion of the ureterocele is dissected in the same plane (see Figs. 41.27D and 41.28B) to the level of the bladder neck, where it is resected. The detrusor muscle is plicated if it is attenuated, and it appears that it may offer insufficient backing. Bladder mucosal flaps are raised to cover the area of the removed ureterocele (see Figs. 41.27E and F and 41.28C).

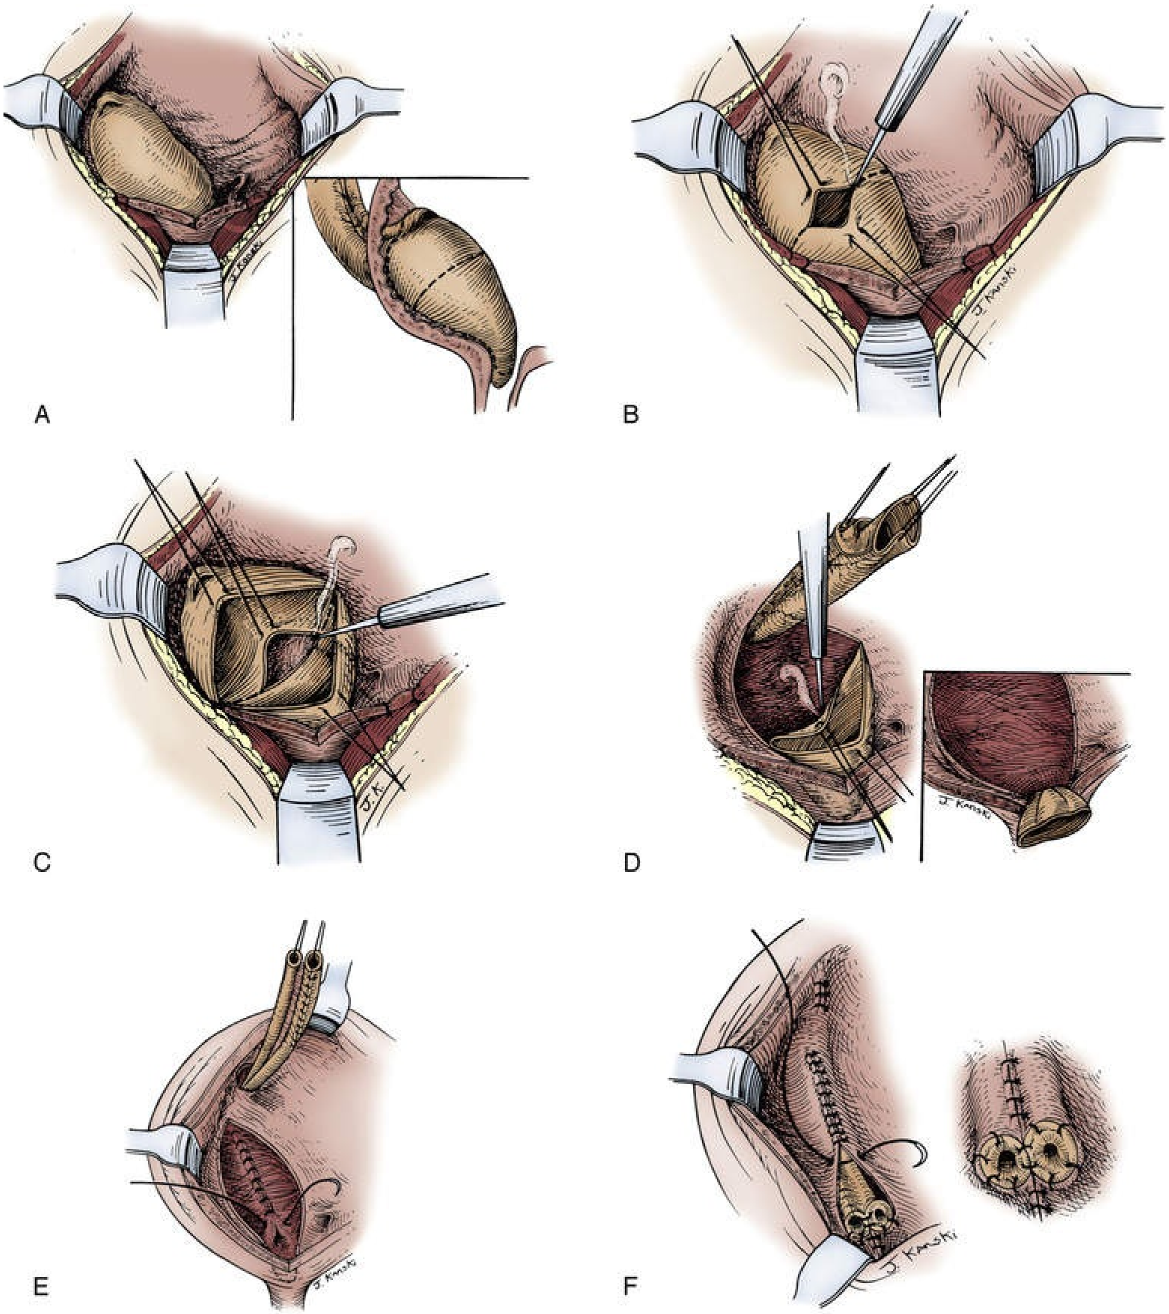

FIG. 41.27 Technique for excision of ectopic ureterocele and common sheath reimplantation of upper and lower pole ureters. (A) Appearance of right-sided ureterocele with open bladder, viewed from below. Note the proximity of the contralateral ureteral orifice. *Inset,* Cutaway side view demonstrating close association of the two polar ureters with a common vascular supply. The *dotted line* indicates the planned initial incision of the ureterocele. (B) After stay sutures are placed, the ureterocele is incised with electrocautery in a transverse direction, exposing the inner cavity of the ureterocele. (C) The posterior mucosal wall of the ureterocele is incised transversely, revealing the often thinned posterior muscular wall of the bladder. This incision is then continued around the bladder mucosal edge

of the ureterocele including the orifice of the lower pole ureter. Stay sutures are important to provide adequate exposure. (D) The upper and lower pole ureters have been mobilized and are retracted into the bladder. The distal aspect of the ureterocele is mobilized in a similar fashion. The bladder mucosal surface is also incised around the edge of the ureterocele to permit complete removal of the ureterocele. *Inset,* The fully mobilized distal ureterocele is retracted caudally, revealing its narrowing attachment at the bladder neck. (E) The dilated upper pole ureter associated with the ureterocele is tapered and remains in continuity with the lower pole ureter. Both are brought into the bladder through a newly formed muscular hiatus to provide adequate tunnel length for the ureteral reimplantation. The thinned-out posterior bladder wall is repaired with multiple interrupted sutures to provide adequate muscular backing for the ureters. The bladder mucosa surrounding the ureterocele defect is mobilized to permit covering of the ureters. (F) *Left,* The ureters are reimplanted into the new ureteral tunnel, sutured distally after spatulation, and covered with bladder mucosa. The lower pole orifice is medial. *Right,* Final appearance of the ureteral tunnel after completion of the reimplantation.

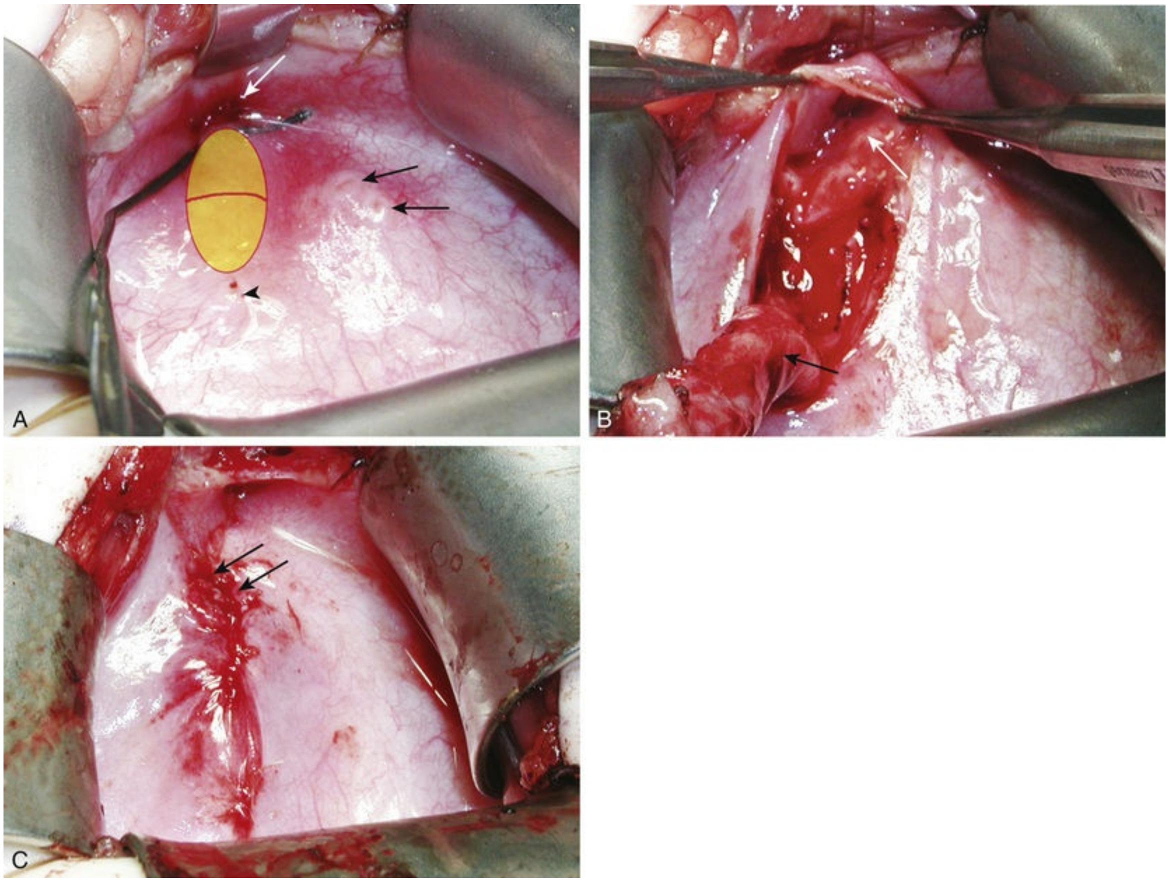

FIG. 41.28 Operative view of ureterocele excision and common sheath reimplantation. (A) View of the decompressed ureterocele *(yellow ellipse)*

after incision (*white arrow* indicates site of incision and the bladder neck orifice) and marking of extent of the ureterocele and the lower pole orifice *(black arrowhead).* The contralateral duplicated ureteral orifices are indicated by *black arrows.* (B) The ureterocele has been divided, and the lower aspect is visible *(white arrow),* going to the bladder neck. This will be excised and the trigonal floor imbricated. The two ureters have been mobilized and are retracted cephalad *(black arrow).* (C) Completed appearance of the reimplanted two ureters *(arrows).*

Once again, several technical points regarding ureterocele excision and common sheath reimplantation deserve mention. **Separation of the duplicated ureters during intravesical dissection is discouraged because it can lead to injury of the common blood supply running longitudinally between the two ureters.** Plication of the detrusor muscle underlying the ureterocele may be necessary to reinforce any areas of muscle deficiency. Furthermore, **the distal portion of the ureterocele may extend below the bladder neck. Extreme care must be taken in this part of the dissection to avoid injury to the sphincter mechanisms. If the entire ureterocele cannot be excised, it can be fulgurated carefully and closed over with two layers.**

Cecoureteroceles present a unique challenge in ureterocele excision and reimplantation in that the distal aspect of the ureterocele can create an obstructive flap-valve with voiding, acting like a windsock behind the urethra. Options for avoidance of this issue includes resection by gentle retraction of the ureterocele if it is not very large, closure of the opening with two layers of tissue, or fulguration of the lumen to cause collapse and closure. Careful postoperative assessment is needed in any case to identify what can be progressive voiding dysfunction if the remnant cecoureterocele creates obstructive voiding (Fig. 41.29).

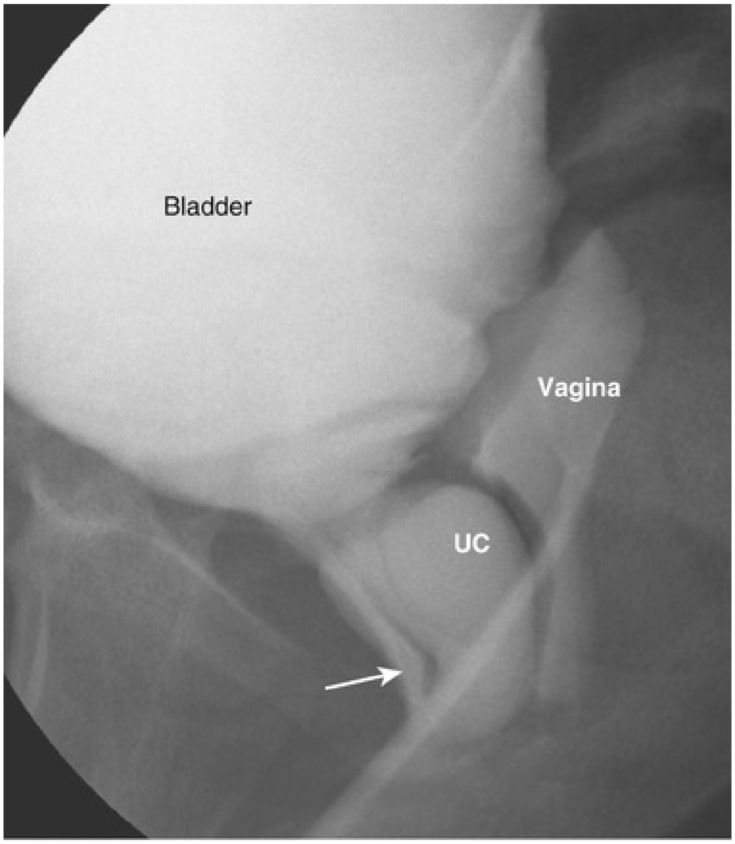

FIG. 41.29 Voiding cystourethrogram demonstrating a large cecoureterocele *(UC)* extending down the urethra and causing bladder outlet obstruction with voiding. The ureterocele fills, acting like an obstructive windsock. The lumen of the urethra is indicated by the *arrow.*

An alternative approach to ureterocele resection is marsupialization, in which the thin intravesical aspect is removed and the edge is sutured. No attempt is made to reinforce the back wall, based on the empirical observation that this is not always needed. Reported results have been satisfactory (Scherz et al., 1989; Lewis et al., 2008). Although this eliminates the need to dissect out the ureterocele and avoids injury to the underlying vagina, it is our impression that this approach has inherent risks that can be avoided by a controlled and predictable surgical approach of trigonal reconstruction. A major problem with marsupialization may be uncommon, but it seems preferable to definitively correct the anatomic and functional defect as certainly as possible on the first open operation when needed.

Reported results of ureterocele excision and common sheath reimplantation are very good, although persisting reflux can be an issue in 5% to 10% of patients. This may be more common when ureteral tapering is needed. Although the clinical significance of this has been called into question, persisting reflux in this context must be viewed with caution.

Key Points: Ureterocele Excision and Reimplantation

- Cecoureteroceles present a unique challenge in ureterocele excision and reimplantation in that the distal aspect of the ureterocele can create an obstructive flap-valve with voiding, acting like a windsock behind the urethra.
- An alternative approach to ureterocele resection is marsupialization, in which the thin intravesical aspect is removed and the edge is sutured.
- The results of ureterocele excision and common sheath reimplantation are very good, although persisting reflux can be an issue in 5% to 10% of patients.
- Total reconstruction including upper pole nephrectomy with ureterocele excision and reimplantation of the lower pole ureter is definitive but is an extensive operation performed with two incisions and may not be necessary in all patients.

Pyeloureterostomy and Ureteroureterostomy

When the upper pole of either an ectopic ureter or ureterocele is to be maintained because of function or surgeon preference, pyeloureterostomy or ureteroureterostomy may be carried out. Both proximal and distal approaches may be used, and these have been described with open and laparoscopic techniques. This management technique has become increasingly used, even in nonfunctioning upper poles, as concerns for long-term problems with hypertension have not been substantiated, and the procedure can be completed through a fairly small incision, often no larger than a herniorrhaphy-type incision (Prieto et al., 2009).

Open Procedure

Ureteroureterostomy can be performed distally to create an anastomosis between the upper pole ureter and the lower pole ureter in an end-to-side fashion. This can be done at the distal ureter via an inguinal, open approach (Huisman et al. 1987; Lashley et al., 2001; Chacko et al., 2007; Prieto et al., 2009). It is critically important in this type of procedure to correctly identify the recipient lower pole ureter, and it is strongly recommended to cystoscopically place a stent into the lower pole ureter at the start of the procedure.

Other options to achieve this goal are the proximal anastomotic technique of ureteroureterostomy or pyeloureterostomy (El Ghoneimi et al., 1998a). This results in the upper pole system draining into the lower pole system. **Such high anastomoses may be preferable to a distal ureteroureterostomy with a dilated upper pole, because the latter may result in more urinary stasis with a distal anastomosis.** Whether the “yo-yo” phenomenon is clinically significant remains uncertain, but we prefer a proximal anastomosis when there is a significant mismatch in ureteral size.

When performing upper tract anastomoses, dissection should be limited to an absolute minimum, especially medially, to prevent disruption of either ureter's blood supply. The upper pole ureter may be considerably larger than the lower pole ureter. A generous longitudinal pyelotomy or ureterotomy is made in the lower recipient pole to overcome such disproportion, and the anastomosis is performed in an end-to-side fashion. The distal portion of the upper pole ureter should be aspirated with a feeding tube to decompress it. The distal upper pole ureter is resected as far inferiorly as possible, with care taken to stay directly on this ureter's wall and avoid the vasculature of the adjacent lower pole ureter. If there is no reflux, the resection is taken as distally as possible and the remnant lower portion of ureter may be left open. If reflux is present in an ectopic ureter, it should be taken as close to the bladder neck as possible. If associated with a ureterocele, it may be possible to avoid resection of the ureterocele as long as it is well decompressed.

Laparoscopic Procedure

Both ureteroureterostomy and pyeloureterostomy can be readily performed laparoscopically (Gonzalez, 2007; Steyaert, 2009), which is aided with robotic control (Kutikov et al., 2007; Smith et al., 2009). A stent is placed in the recipient ureter only and not across the anastomosis (Fig. 41.30). We have reported a series of patients who underwent 25 robotic-assisted laparoscopic ureteroureterostomy (RALUU) procedures and compared it with a series of patients who underwent open ureteroureterostomy during the same period. Operative times and complication rates were comparable, with slightly shorter length of hospitalization in robotic cases. In the robotic cases, cystoscopy with lower pole stenting was consistently performed, however the type of stent varied because of surgeon preference (Lee et al., 2015). Another series with 12 patients who underwent RALUU used an external ureteral stent, which was removed on postoperative day 1. This series similarly showed efficacy of the procedure, with 100% resolution of hydronephrosis postoperatively (Biles et al., 2016).

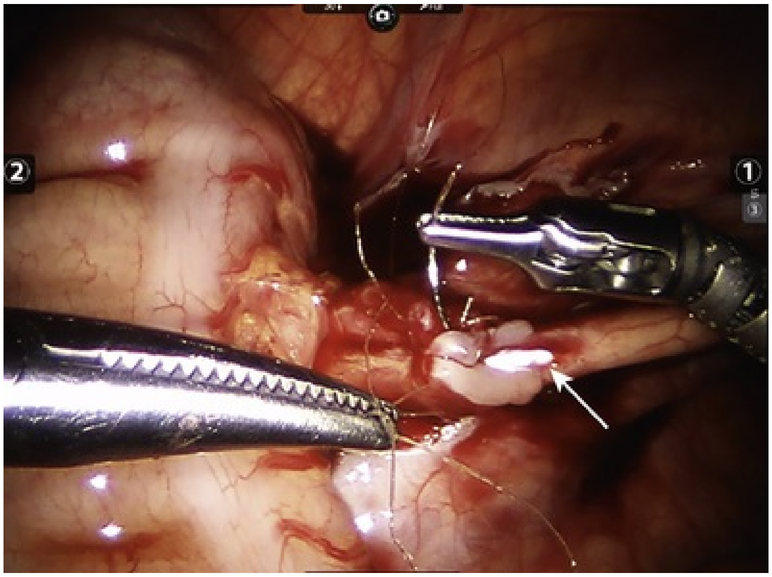

FIG. 41.30 Operative view of robotic ureteroureterostomy for ectopic ureter presenting with incontinence. The procedure is being performed at the level of the iliac vessels. The *arrow* indicates the ureteral stent in the recipient (lower pole) ureter.

Laparoscopy has also been utilized to aid with performing open ureteroureterostomy to improve ease of procedure and minimize size of incision needed for ureteroureterostomy. Grimsby et al. described a technique for identifying the ureters by placing a camera port at the level of the umbilicus for visualization. A babcock was then used through the small incision through which ureteroureterostomy was to be performed to grasp the ureters from the retroperitoneum and deliver them for the surgery (Grimsby et al., 2014). This technique did not increase operative time, and the success of the operation and complication rate was comparable to the traditionally performed procedures.

Key Points: Pyeloureterostomy and Ureteroureterostomy

- Ureteroureterostomy has emerged as a frequently used management technique for the duplicated collecting system with obstructed upper pole in both functioning and nonfunctioning upper poles.
- Size mismatch between the two ureters does not seem to impede achieving a satisfactory anastomosis.

Transurethral Incision for Ureterocele

The simplest means to decompress the obstructed upper pole or single system ureterocele is TUI. Reported rates of relief of obstruction range from 78% to 97% (Rich et al., 1990; Jayanthi and Koff, 1999; Di Renzo et al., 2010; Adorisio et al., 2011; Palmer et al., 2011; Castagnetti et al., 2013). A comparison between TUI and multiple punctures (watering can technique) showed no difference in decompression rates, although multiple punctures induced less reflux into the affected ureter. In the setting of acute sepsis, TUI is the most appropriate intervention, although a percutaneous nephrostomy would be a viable option as well.

Although TUI can reliably relieve obstruction, it carries the risk for inducing reflux into the affected ureter, which may then predispose to upper tract infection and the need for reconstruction. The balance between the minimal morbidity of TUI and its uncertainty is the basis for the clinical controversy as to its usefulness.

Our preferred method of incising the ureterocele is similar to the one described by Rich et al. (Rich et al., 1990): a transverse incision through the full thickness of the ureterocele wall using the cutting current. Making the incision as distally on the ureterocele and as close to the bladder floor as possible lessens the chance of postoperative reflux into the ureterocele. One can use either a Bugbee electrode or an angled-tip wire. We favor the latter instrument because it has a finer tip and allows for more precision, and the angle allows for easier manipulation. In older children, the resectoscope with the Collins hot knife may be used to make the incision. Laser incision has been reported with equivalent results (Marr and Skoog, 2002; Jankowski and Palmer, 2006; Ilic et al., 2018). Cold knife incision has been used as well. The watering can technique has also been recently described (Palmer et al., 2011; Haddad et al., 2017; Ilic et al., 2018).

The ureterocele should be incised deeply because ureteroceles may be thick walled. Adequacy of ureterocele incision is confirmed either by the escape of a jet of urine from the ureterocele or by viewing the urothelium on the inside of the ureterocele (Fig. 41.31). For the ectopic ureterocele that extends into the urethra, adequate drainage may be achieved by either a longitudinal incision that extends down from the intravesical portion into the urethral portion or by two separate punctures, one in the intravesical portion of the ureterocele and one in the urethral portion of the ureterocele.

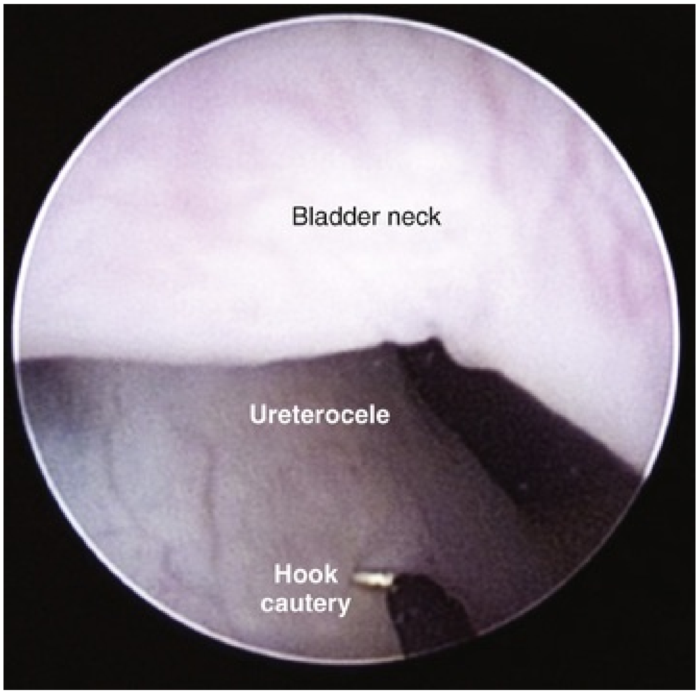

FIG. 41.31 Endoscopic image of a ureterocele about to be incised with hook cautery. The incision should be made inferiorly and medially to limit the risk for reflux, but the key goal is decompression. The ureterocele should be incised with the bladder partially filled, but not so much as to efface the ureterocele.

In the uninfected well child, no bladder catheter is left in place, and most children are treated as outpatients. A follow-up ultrasonography is performed in 4 to 6 weeks to assess the degree of decompression (Fig. 41.32). A voiding cystogram is performed in 2 to 3 months to determine the status of lower pole reflux and whether new reflux has been created into the ureterocele (Fig. 41.33).

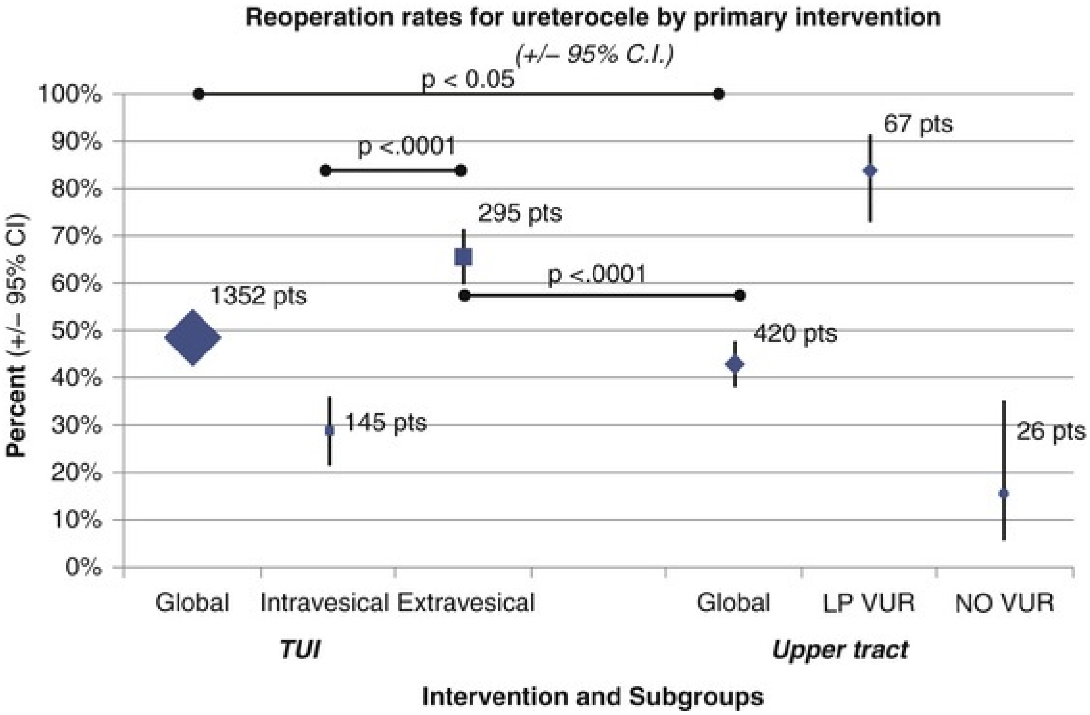

FIG. 41.32 Chart indicating incidence of secondary surgery after either transurethral incision *(TUI)* or upper tract approach (partial nephrectomy or ureteroureterostomy) based on data from multiple sources. The number of patients *(pts)* is indicated adjacent to the data points. Statistical differences are indicated between selected groups based on two-tailed Fisher exact testing. *CI,* Confidence interval; *LP,* lower pole; *VUR,* vesicoureteral reflux.

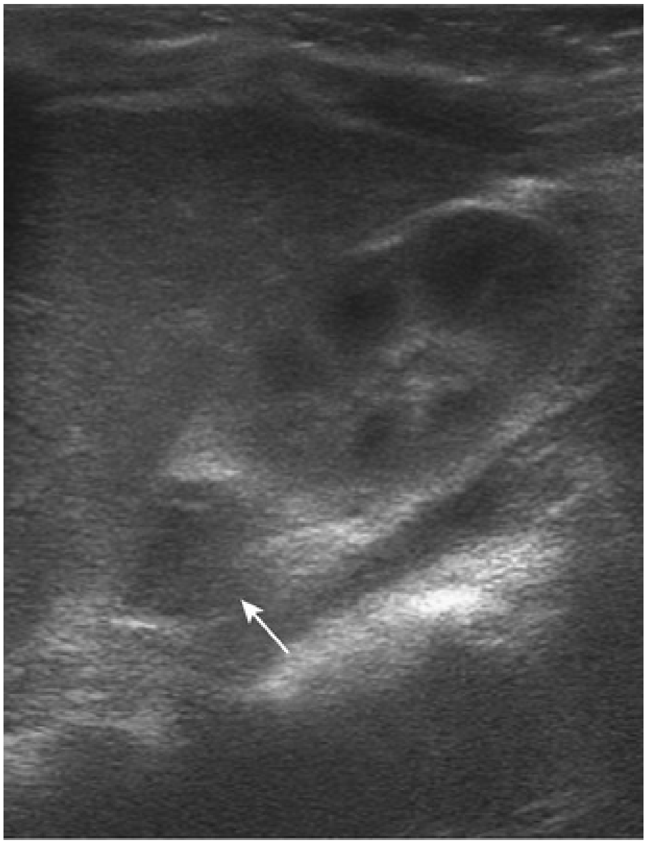

FIG. 41.33 Appearance of the decompressed upper pole *(arrow)* in same patient as in Fig. 41.9, following endoscopic incision of the ureterocele.

The reported incidence of new reflux ranges from 0% to 50%. The risk for reflux may be dependent on the method used for incision (Fig. 41.34) (Tank, 1986; Rich et al., 1990; Blyth et al., 1993; Jelloul et al., 1997; Dahm and King, 1998; Husmann et al., 1999; Jayanthi and Koff, 1999; Shekarriz et al., 1999; Cooper et al., 2000; Singh and Smith, 2001; Upadhyay et al., 2002; Chertin et al., 2007; Rich et al., 1990; Husmann et al., 1999; Jayanthi and Koff, 1999; Shekarriz et al., 1999; Cooper et al., 2000; Singh and Smith, 2001; Upadhyay et al., 2002; Chertin et al., 2007; Di Renzo et al., 2010; Adorisio et al., 2011; Palmer et al., 2011; Castagnetti et al., 2013). Some authors favor puncture instead of incision, but no data are available that demonstrate a clear difference. **The type of ureterocele is a clear determinant of the outcomes of TUI, with intravesical ureteroceles having the highest likelihood of achieving all therapeutic goals with only the incision. Decompression with no reflux can be achieved in 70% to 80% of patients. Extravesical ureteroceles, however, are more likely to have persisting or new reflux and may require secondary surgery based on the presence of reflux in 70% by**

some series (Chowdhary et al., 2017; Hodhod et al., 2017). In the meta-analysis by Byun and Merguerian, the presence of lower pole reflux and the location of the ureterocele are similar in their impact on outcomes (Byun and Merguerian, 2006). In this analysis, the relative risk for reoperation was 1.74 times greater in the presence of reflux than without, and 2.78-fold times higher if extravesical. These factors did not seem to be additive, suggesting they represented similar underlying causes. In comparison with an open approach of any modality, however, the simplicity of ureterocele incision coupled with the potential for definitive cure, even if not in a large fraction, is appealing. **TUI also acts to better prepare the patient for a secondary major surgery, if needed, by decompressing dilated ureters.**

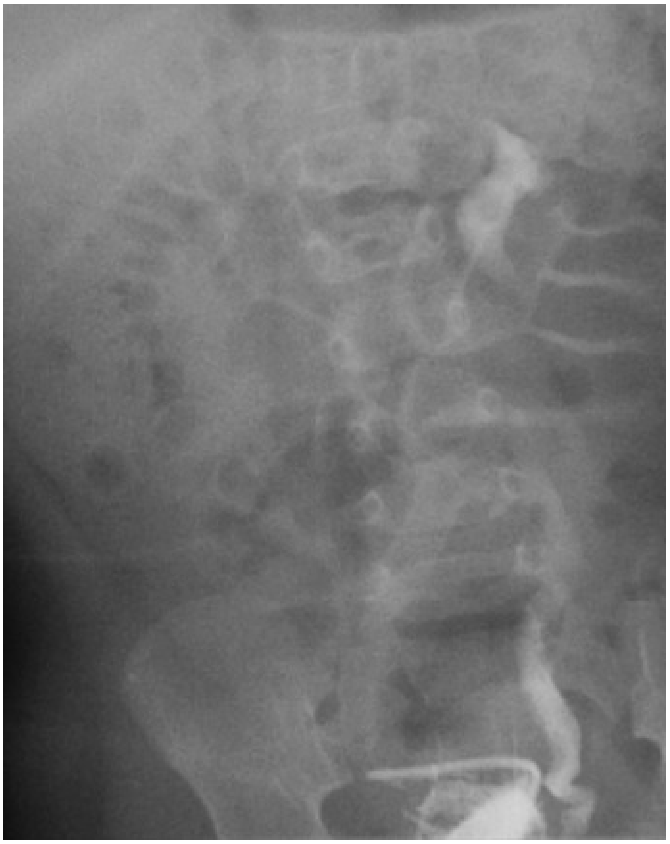

FIG. 41.34 Voiding cystourethrogram demonstrating reflux into the upper pole of a duplex system after ureterocele incision. This type of reflux will rarely resolve spontaneously. Although the clinical risk is uncertain, the reflux is most often repaired.

Reflux Outcomes After Transurethral Incision

The natural history of lower pole reflux after TUI is incompletely defined. In some series an observational approach has been taken, and resolution has been reported in a few series with variable follow-up (Jesus et al., 2011). Sander et al. reported cure rates (improvement of hydronephrosis and absence of VUR) of 55.6% in patients with single-system ureterocele and 14.9% in those with duplex-system ureterocele. Rates of *de novo* reflux into the ureterocele moiety were 27.8% for patients with single-system ureterocele and 56.2% for those with duplex-system ureterocele (Sander et al., 2015; Jawdat et al., 2018). The usefulness of observing these patients is dependent on occurrence of infection and parental preferences.

Key Points: Transurethral Incision of Ureterocele and Drainage Procedures

- The reported incidence of new reflux after TUI of a ureterocele ranges from 0% to 60% and may be dependent on the method used for incision.
- The type of ureterocele is a clear determinant of the outcomes of TUI, with intravesical ureteroceles having the highest likelihood of achieving all therapeutic goals with only the incision.
- TUI also acts to better prepare the patient for a secondary major surgery, if needed, by decompressing dilated ureters.
- Persisting reflux into the upper or lower poles is typically an indication for ureterocele excision and reimplantation, but resolution has been reported.
- In general, it has not been possible to predict with any accuracy how an individual might respond to TUI based on clinical parameters.
- The ectopic ureter in a neonate with sepsis or with massive dilation may be best managed with a temporary end ureterostomy.
- Ureteroureterostomy can be performed distally or proximally to create an anastomosis between the upper pole ureter and the lower pole ureter in an end-to-side fashion.

Ureterostomy for Ectopic Ureter

The ectopic ureter in a neonate with sepsis or with massive dilation may be best managed with a temporary end ureterostomy, although drainage with either endoscopic ureteral incision and stenting or nephrostomy tube is also an option (El Ghoneimi et al., 1996; Ortiz et al., 2017). **This has the advantage of permitting acute decompression to manage sepsis and permit later assessment of any function in the affected renal unit before definitive management.** By performing an end ureterostomy, the ureter can decompress, and it is in position to be reimplanted if the renal unit is felt to be salvageable. No resection of redundant ureter is performed because this will shorten in time, and some length will be needed to perform the reimplantation. The stoma should be positioned at what would be the lateral end of a Pfannenstiel incision. Percutaneous ureterostomy has been reported as well (Bilen et al., 2006). Assessment of functional status is performed shortly before definitive surgery, usually in 4 months or after 6 months of age. DMSA scanning is probably the most efficient means, but differential urine collection is an option as well. If there is no function appreciable, partial or total nephrectomy is performed with removal of the entire ureter to the stoma.

Summary of Clinical Decision Making

For ectopic ureters, clinical decision making is much more straightforward than for ureteroceles and rests on whether to maintain the upper pole of a duplex system. If this is chosen, then the surgical approach depends on the presence of reflux in the lower pole; if present, a common sheath reimplantation or a lower pole reimplantation with distal upper to lower pole ureteroureterostomy is performed. If there is no lower pole reflux, either proximal or distal ureteroureterostomy is performed. If the degree of function is ambiguous, a temporary end ureterostomy can be used to permit assessment out of the acute setting, particularly with a massively dilated ureter. Also, if reflux is present, the need for lower surgery to correct the reflux may influence the choice to avoid upper tract surgery. If removal of the upper pole is chosen based on degree of dilation or the preference for removal of nonfunctioning, dysplastic tissue, an upper pole nephrectomy is performed. For the single-system ectopic ureter, preservation or removal is also based on degree of function and surgeon preference. There are no objective outcome data to advocate clearly for one or another approach.

For a ureterocele in a duplex system, the availability of endoscopic incision creates more options (Table 41.1; see Fig. 41.34). It is important to recognize that although TUI is an operation, it is of a totally different nature than either an upper pole nephrectomy or a lower tract reconstruction. It is inappropriate to equate them as operations in a comparative manner. **In general, it has not been possible to predict with any accuracy how an individual might respond to TUI based on clinical parameters.** Because in some patients significant lower pole reflux and upper tract dilation may be treated with a brief outpatient procedure with documented long-term results, it would seem reasonable to offer this option before moving directly to a more complex upper or lower tract reconstruction. **Even if one-half of these patients may need subsequent surgery, it can be safely deferred until the child is older. There is also the further appeal of TUI in that it may make a subsequent surgical procedure less complex by decompressing a dilated upper pole ureter.** Reimplantation may be much more effective and not require excisional tapering. This lessens overall morbidity, another goal of management. The appeal of TUI may therefore be less in the older child with a massive upper pole in whom removal may be preferable and definitive surgery can be performed at diagnosis.

TABLE 41.1

Options for Ureterocele Management

PROCEDURE	IDEAL INDICATIONS	ADVANTAGES	LIMITATIONS
Transurethral incision	• Infant • Large ureterocele with VUR	• Outpatient procedure • Effective decompression • Occasionally definitive	• May produce reflux into ureterocele segment, necessitating bladder surgery
Upper pole nephrectomy	• Older patient • Large nonfunctioning upper pole • No VUR	• May be definitive • Removes pathology • Avoids bladder-level surgery	• May not be definitive • Significant surgery • Risk to lower pole • May still require lower surgery in bladder
Ureteroureterostomy or ureteropyelostomy	• Older patient • Functioning upper pole • No VUR	• Drains obstructed segment with little risk for obstruction or UTI	• Leaves ureterocele in bladder • May develop reflux
Ureterocele excision and common sheath reimplantation	• Reflux • Functioning upper pole	• Eliminates obstruction and reflux	• Complex surgery • Risk to vagina and bladder neck

	without significant dilation	• Removes ureterocele • No renal risk	• May require ureteral tapering

Voiding Dysfunction after Ureterocele Repair

Voiding dysfunction after lower urinary tract reconstruction for ureterocele has been reported in some series, but with a low incidence (Abrahamsson et al., 1998; Sherman et al., 2003; Lewis et al., 2008). In other series, there was no evidence of incontinence or significant bladder dysfunction (de Jong et al., 2000; Vereecken and Proesmans, 2000; Beganovic et al., 2007). Abrahamsson et al. reported infrequent voiding with the possibility of infection in 19 of 36 patients, whereas 3 of 36 demonstrated incontinence (Abrahamsson et al., 1998). Vereecken and Proesmans made a similar observation with a lower incidence after complex bladder surgery for duplication anomalies (Vereecken and Proesmans, 2000). Abrahamsson suggested that the bladder dysfunction was the result of an intrinsic bladder abnormality rather than the surgical procedures.

In the child with either recurrent infections or incontinence after surgical repair of a ureterocele, one must consider the type of surgery and if there was the possibility of inadequate trigonal support. This can lead to a weak bladder base, ballooning of the trigone posterior to the bladder neck, and an obstructive process. This can also occur after TUI of a ureterocele with a urethral component. Inadequate bladder emptying and infection as well as upper tract dilation can result.

A VCUG may be needed to assess the bladder anatomy with voiding, and video-urodynamics may be needed. It would be important to recognize the need for lateral views during voiding to identify the bladder pathology. We have also used antegrade cystoscopy via a suprapubic puncture to better assess the bladder neck. Recurrent VUR may occur, particularly if there is obstructed voiding.

Managing bladder dysfunction after ureterocele repair will depend on the cause and may include bladder and trigonal reconstruction or bladder neck repair, intermittent catheterization, or, if there is evidence of bladder neck incompetence, endoscopic injection of bulking agents.

Other Ureteral Anomalies

Anomalies of Number

Bifid Ureters

Ureteral duplication may be associated with ectopia or a ureterocele but is also compatible with a normally functioning renal system if both ureters enter orthotopically or if there is partial duplication. Ureteral duplication is a common condition, described in approximately 1 in 125 people (0.8%) based on autopsy series, which tend to be less selective (Nation 1944; Kaplan and Elkin, 1968; Timothy et al., 1971; Privett et al., 1976). There is a slightly higher incidence in females, estimated to be approximately 1.6 : 1. Duplication is unilateral six times more frequently than bilateral; however, it is clinically prudent to carefully look for contralateral duplication when unilateral duplication is documented. This may be critical in the setting of nonhydronephrotic upper poles and ureteral ectopy causing incontinence. Right and left sides appear to be affected similarly with unilateral duplication.

A bifid renal pelvis includes only a single ureter, but confluence of the upper and lower ureters lower than the UPJ constitutes partial duplication of the ureter or bifid ureter.

An increased incidence of ureterorenal pathology has been documented with duplication anomalies. The clinical implication of duplication depends largely on the ureteral insertion. **A useful clinical approach is to consider that conditions that routinely affect the single-system kidney are those that affect the lower pole, including UPJ obstruction and VUR. The upper pole is more likely affected by conditions resulting from abnormal ureteral formation, including ectopic and ureterocele as discussed earlier.**

Lower pole UPJ obstruction evaluation and management are similar to those for a single-system UPJ obstruction. Lower pole UPJ obstruction may be identified with partial and complete ureteral duplication. Recognition of the presence of the duplication may be challenging with massive hydronephrosis, but in most cases the normal upper pole will be identified on functional imaging such as a renal scan, even if not detected on ultrasonography. Lower pole UPJ obstruction may resolve spontaneously, just as a single system with comparable severity of dilation. Repair may be optionally accomplished with pyeloureterostomy of the dilated renal pelvis of the lower pole to the normal upper pole ureter.

Upper pole UPJ obstruction has been reported, including in association with lower pole UPJ obstruction, but is exceptionally rare (Ho et al., 1995; Ng, 1999; Peters and Pathak, 2014).

Hydronephrosis of the lower pole moiety may also represent VUR, and this is often of high grade. The presence of a dilated ureter on ultrasonographic evaluation will usually be present. This rarely represents ureterovesical obstruction and more often indicates VUR. Lower pole VUR is often associated with significant functional reduction in the lower pole, which is usually congenital but may also be associated with prior infection. Evaluation and management are similar to reflux into a single system, but spontaneous resolution may be more delayed (Afshar et al., 2005). Common sheath ureteral reimplantation and endoscopic injection are surgical options, as well as low ureteroureterostomy of the refluxing lower pole ureter to the upper pole ureter.

Triplication

Triplication of the ureter, either complete or partial, is very rare. These conditions typically have manifested with infection or wetting. The classification by Smith remains useful, in which triplex ureters are divided into four types (Smith, 1946). Type 1 constitutes three entirely separate ureters with unique attachment to the bladder or distally and accounts for 35% of triplications. Type 2 is an incomplete separation with two ureteral orifices, occurring in 21%. Type 3 is a trifid ureter with a single ureteral orifice, seen in 31%. Type 4 describes two ureters with three orifices, seen in 13%. This occurs with an inverted-Y bifurcation similar to that described for duplicated ureters. The positioning of the ureteral orifices typically follows the Weigert-Meyer law (Zaontz and Maizels, 1985).

The ureters may be associated with ureteroceles and may be ectopic to the bladder neck, urethra, or vagina (Park, 2008; Engelstein et al., 1996; Patel et al., 2001). Lower pole and mid-pole UPJ obstruction may be present, as well as ureterovesical obstruction (Sivrikaya et al., 2007; Merlini, 1983). VUR is also described, as well as contralateral duplication (Ander et al., 1997; Srivastava et al., 1996). Fusion anomalies may be present in some patients (Pode et al., 1983; Golomb and Ehrlich, 1989).

Quadruple Ureters

Even more rare is ureteral quadruplication, with only eight cases reported. Most have been in adults, but three recent cases included four ureters draining into a large ureteral cyst and connecting to the bladder through a single ureter (Klinge et al., 2001; Vicentini et al., 2007; Koszutski et al., 2008). One report of a young adult with incontinence describes three of the four ureters merging and entering the bladder orthotopically and the fourth ureter draining to the perineum. This ectopic ureter was associated with the lower mid-calyx, contrary to what the Weigert-Meyer law would predict.

Fibroepithelial Polyps

Polyps of the ureter may manifest clinically with flank pain or hematuria or by incidental detection of hydronephrosis. The most common site of attachment is at the UPJ, although they may originate from any part of the ureter. As a cause of UPJ obstruction, they are very uncommon, reported as 0.5% of all UPJ patients undergoing pyeloplasty (Adey et al., 2003; Kojima et al., 2011). A very large majority of patients were male (89%), and a majority of polyps occurred on the left side (78%). They are uncommonly bilateral, but this has been reported with clinical effects on both kidneys (Bartone et al., 1990; Lavelle et al., 1997; Bhalla et al., 2002; Adey et al., 2003; Romesburg et al., 2009). In a recent series, two of nine patients had bilateral clinically obstructive UPJ polyps. They may also be multiple. We have seen one case in which the polyp protruded from the urethra and produced severe voiding symptoms and was ultimately found to originate from the proximal third of the ureter.

Smaller polyps may not be evident on modern imaging and in a recent series were detected in 22% of patients before surgery for UPJ obstruction (Adey et al., 2003). Ultrasonography may be useful in detecting these polyps (Wang et al., 2012). They would usually be seen on intravenous pyelography but may be mistaken for ureteral blood clots, particularly in the setting of hematuria (Fig. 41.35). Filling defects on retrograde pyelography in anticipation of a pyeloplasty should trigger a search for the polyps (Fig. 41.36). It is unlikely that this would alter the surgical approach unless the polyp was significantly distal to the UPJ.

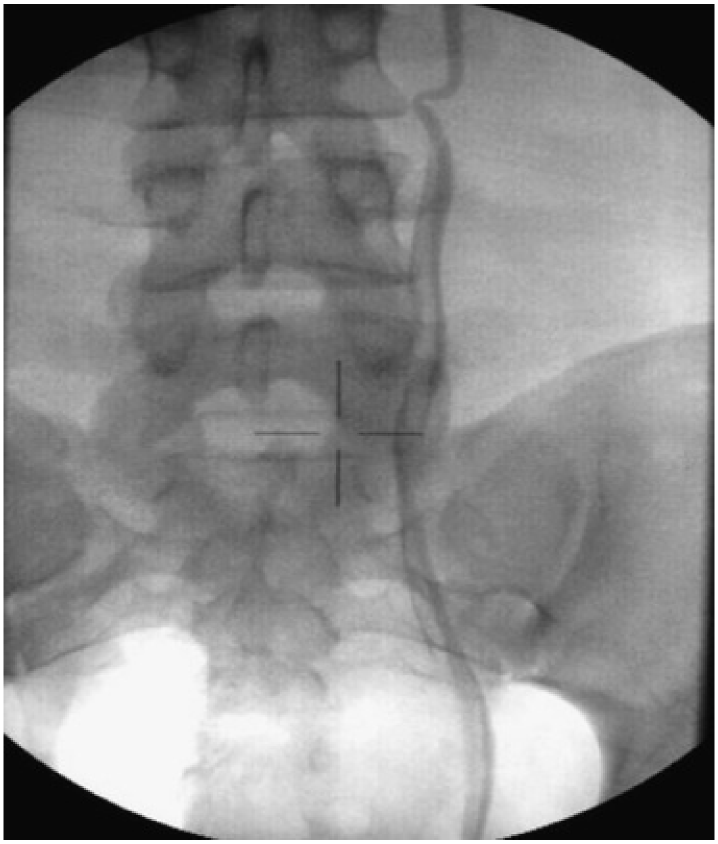

FIG. 41.35 Retrograde ureterogram of an adolescent with a history of hematuria, dysuria, and a fleshy mass protruding from her urethra. The distal segment had been resected by an outside physician. The long-filling defects are typical of fibroepithelial polyps but may be confused for blood clots.

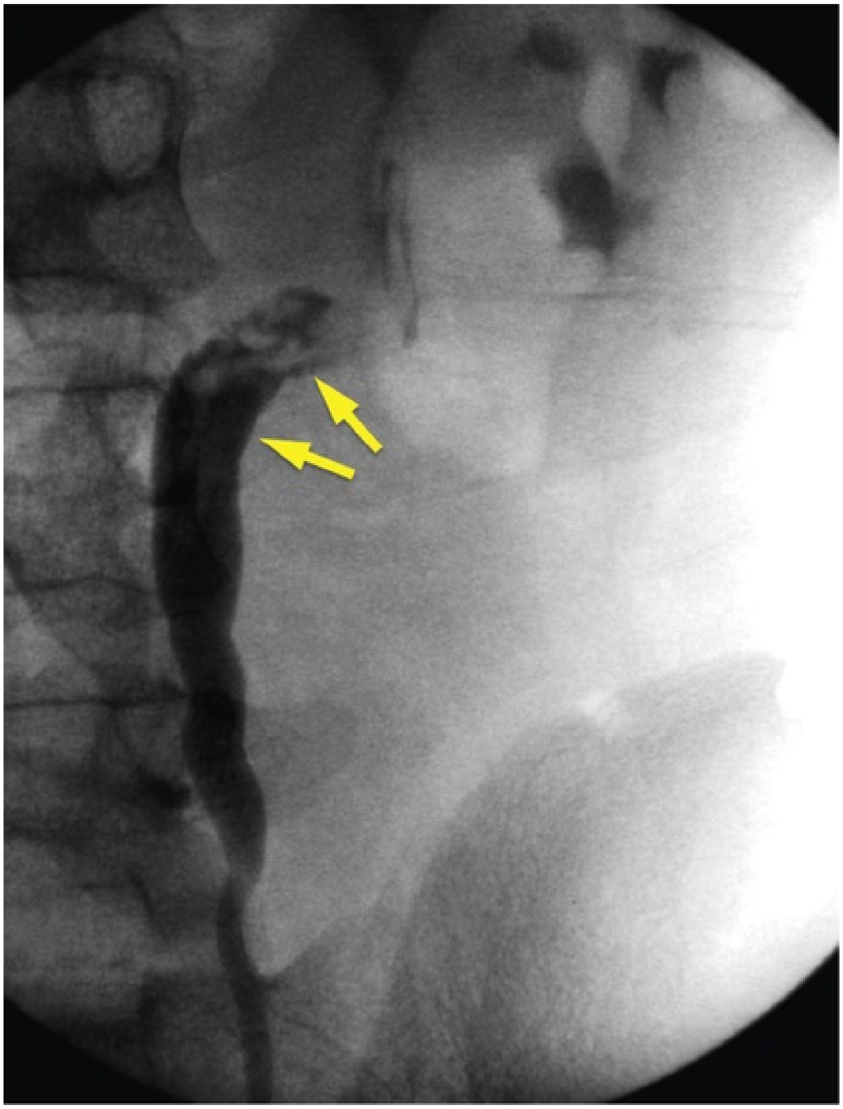

FIG. 41.36 Retrograde pyelogram demonstrating complex filling defects at the ureteropelvic junction in a child with intermittent flank pain and hydronephrosis. The *arrows* show the filling defect at the ureteropelvic junction and the proximal ureter, suggesting a complex multifrondular fibroepithelial polyp.

The cause of fibroepithelial polyps is unclear, although progressive traction resulting from ureteral peristalsis may promote edema and growth. We have seen one in which the ureter was being intussuscepted into itself owing to traction on the polyp in the mid-ureter. Histologically, they are considered benign neoplasms with fibroepithelial and vascular elements, with overlying normal to hypertrophied urothelium. There is usually a fibrovascular core with significant stromal edema. Little inflammation is seen.

Management of the polyp is dictated by the presentation and location. **For**

polyps at the UPJ, most have undergone pyeloplasty, although the question of whether simple endoscopic resection might suffice is not settled, as there are too few cases. Ureteroscopic removal of ureteral polyps is the recommended therapy away from the UPJ, based on combined adult and pediatric reports (Minevich et al., 2005; Childs et al., 2009; Iwatsuki et al., 2010). Earlier reports advocated sleeve resection and reanastomosis of the ureter to prevent recurrence, yet the persisting success with ureteroscopic resection would suggest that to be unnecessary. Even earlier reports recommended nephrectomy, which cannot be justified.

Key Points: Other Ureteral Anomalies

- Ureteral duplication is compatible with a normally functioning renal system if both ureters enter orthotopically or if there is partial duplication.
- It is clinically prudent to look for contralateral duplication when unilateral duplication is documented.
- An increased incidence of ureterorenal pathology has been documented with duplication anomalies.
- Conditions routinely affecting a single system kidney are those that affect the lower pole, including UPJ obstruction and VUR; the upper pole is more likely affected by conditions resulting from abnormal ureteral formation, including ectopia and ureterocele.
- Polyps of the ureter may manifest clinically with flank pain or hematuria or by incidental detection of hydronephrosis.
- The most common site of attachment of a fibroepithelial polyp is at the UPJ, although they may originate from any part of the ureter.
- UPJ polyps are best treated with pyeloplasty, although the question of whether endoscopic resection might suffice is not settled.
- Ureteroscopic removal of ureteral polyps is the recommended therapy away from the UPJ.

Anomalies of Position

Vascular Anomalies Involving the Ureter

A variety of vascular lesions can cause ureteral obstruction. With these lesions, the vascular system rather than the urinary system is anomalous. With the exception of accessory renal blood vessels, all of these lesions are relatively uncommon, although all have clinical relevance.

Preureteral Vena Cava

Anatomy.

Preureteral vena cava is commonly known to urologists as *circumcaval* or *retrocaval ureter,* terms that are anatomically descriptive but misleading with regard to development (Lerman et al., 1956; Dreyfuss, 1959). **The term *preureteral vena cava*** emphasizes that the circumcaval ureter results from altered vascular, rather than ureteral, development. This is the more accurate term.

This disorder involves the right ureter, which typically deviates medially behind (dorsal to) the inferior vena cava, winding about and crossing in front of it from a medial to a lateral direction, to resume a normal course, distally, to the bladder. The renal pelvis and upper ureter are typically elongated and dilated in a *J* or fishhook shape before passing behind the vena cava. The collecting system is not inevitably obstructed. Circumcaval ureters can be classified into two clinical types (Bateson and Atkinson, 1969; Kenawi and Williams, 1976). The more common type I has hydronephrosis and a typically obstructed pattern demonstrating some degree of fishhook-shaped deformity of the ureter to the level of the obstruction. Type II has a lesser degree of hydronephrosis or none at all. Here, the upper ureter is not kinked but passes behind the vena cava at a higher level, with the renal pelvis and upper ureter lying almost horizontal before encircling the vena cava in a smooth curve. In type I, the obstruction appears to occur at the edge of the iliopsoas muscle, at which point the ureter deviates cephalad before passing behind the vena cava.

Embryology.

The definitive inferior vena cava develops on the right side from a plexus of fetal veins (Fig. 41.37). Initially, the venous retroperitoneal pathways consist of symmetrically placed vessels, both central and dorsal. The posterior cardinal and supracardinal veins lie dorsally, and the subcardinal veins lie ventrally. These channels, with their anastomoses, form a collar on each side through which the ascending kidneys pass. Normally the left supracardinal veins and the lumbar portion of the right posterior cardinal vein atrophy. The subcardinal veins become the internal spermatic veins. The definitive right-sided inferior vena cava forms from the right supracardinal vein. **If the subcardinal vein in the lumbar portion fails to atrophy and becomes the primary right-sided vein, the ureter is trapped dorsal to it.**

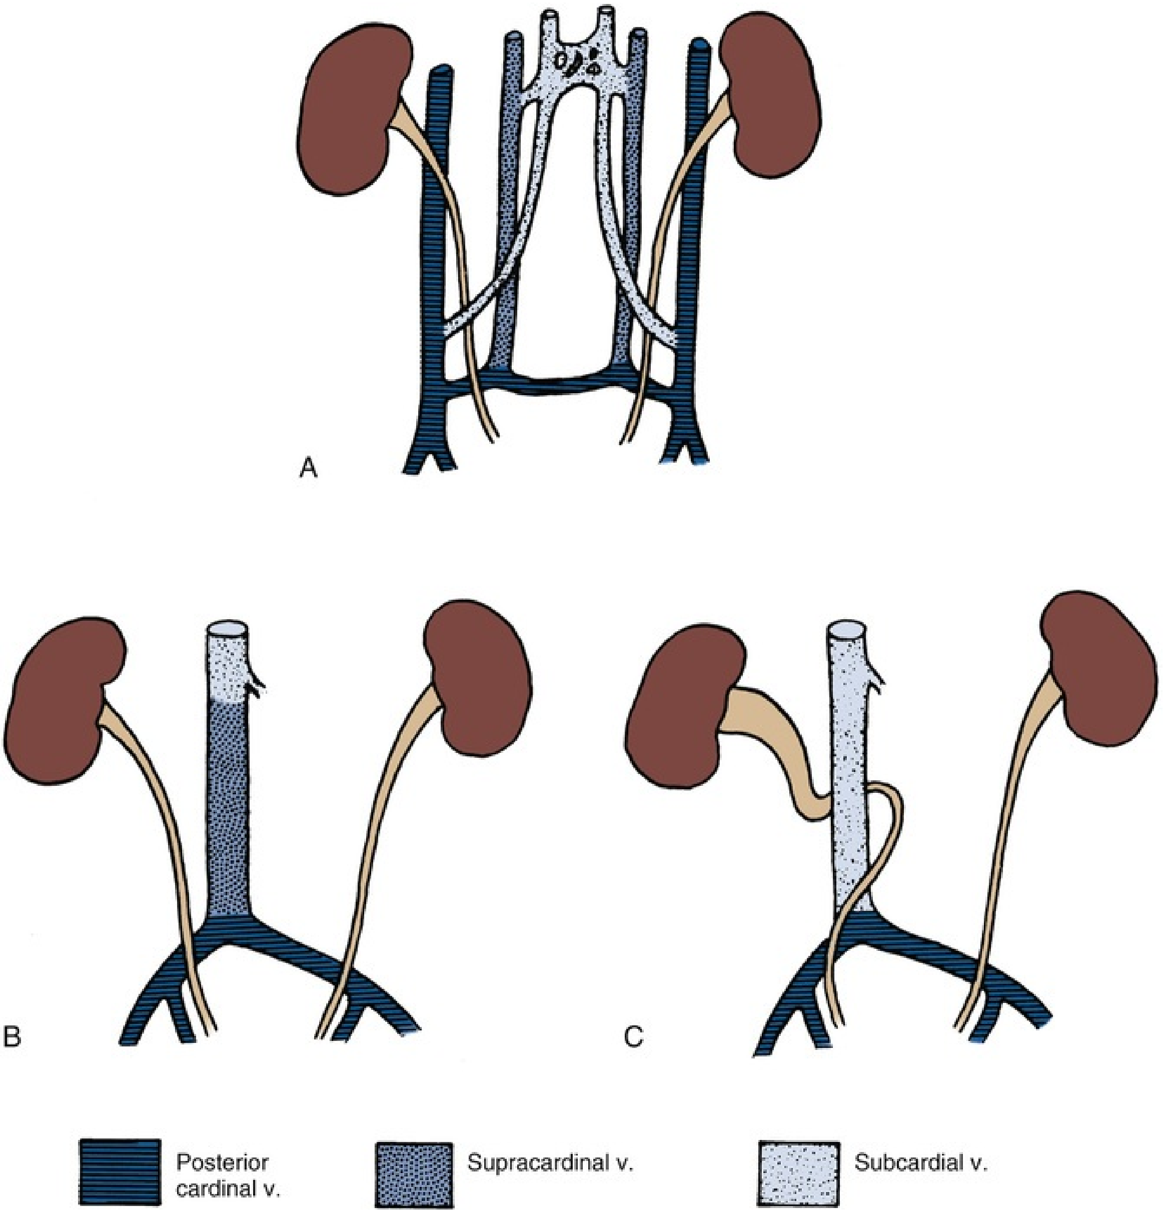

FIG. 41.37 Fetal venous ring (A), normal vena cava (B), and preureteral vena cava (C). (Redrawn from Hollinshead WH. *Anatomy for surgeons.* vol 2. New York, NY: Hoeber Medical Division of Harper and Row; 1956.)

When the definitive vena cava forms normally and the ventral portion of the primitive ring also persists, a double right vena cava is formed because of the persistence of both the right subcardinal vein dorsally and the right subcardinal vein ventrally. This double vena cava traps the right ureter between its limbs (Sasai et al., 1986).

Although bilateral vena cava or left-sided vena cava can occur, a bilateral circumcaval ureter has been described in a case of situs inversus (Clements et al., 1978; Mayo et al., 1983; Brooks, 1962). In cases of bilateral vena cava associated with a circumcaval ureter, the circumcaval ureter has been reported only on the right side, denoting that the right vena cava developed abnormally from a persistent subcardinal vein, whereas the left vena cava developed from the left supracardinal vein but otherwise normally (Pick and Anson, 1940).

Incidence.

The incidence of preureteral vena cava at autopsy is about 1 in 1500. The anomaly is three to four times more common in male than in female cadavers, although a literature review reported a ratio of 114 : 41 male to females (2.8 : 1) (Heslin and Mamonas, 1951; Kenawi and Williams, 1976).

The symptoms of preureteral vena cava are those of obstruction. **Although the lesion is congenital** (Soundappan and Barker, 2004; Acharya et al., 2009)**, presentation in most patients does not occur until the third or fourth decade of life** (Kenawi and Williams, 1976).

Diagnosis.

Clinically, patients may have symptoms of flank or abdominal pain or infection, or the disorder may be discovered incidentally during other radiologic tests. Excretory urography often fails to visualize the portion of the ureter beyond the J hook (i.e., extending behind the vena cava), but retrograde ureteropyelography demonstrates an S curve to the point of obstruction with the retrocaval segment lying at the level of L3 or L4 (Kenawi and Williams, 1976). Cavography is no longer a necessary diagnostic test.

Ultrasonography and CT or MRI also have been useful in defining the vascular malformation (Murphy et al., 1987). CT urography may be the procedure of choice to confirm the diagnosis and avoid retrograde ureteropyelography (Sasai et al., 1986; Kellman et al., 1988). Nuclear renal furosemide scanning can categorize the anomaly as obstructed or nonobstructed (Pienkny et al. 1999) **MRI can demonstrate the course of a preureteral vena cava and may be a more detailed and less invasive imaging modality when**

compared with CT and retrograde pyelography (Uthappa, Anthony et al. 2002).

The diagnosis may not be obvious and we have seen one case in which the obstruction from a pre-ureteral cava was thought to be a ureteropelvic junction obstruction and subsequent pyeloplasty that failed (Junejo et al., 2018).

Treatment.

Surgical correction involves ureteral division, with relocation and ureteroureteral or ureteropelvic reanastomosis, usually with excision or bypass of the retrocaval segment, which can be aperistaltic. It is important to be mindful of the ureter's blood supply from the renal artery and aorta superiorly and the iliac vessels inferiorly. As stated earlier, the preferred approach for the obstructed ureter is ureteral division and relocation. Laparoscopic (Miyazato et al., 2002; Ramalingam and Selvarajan, 2003; Tobias-Machado et al., 2005; Fernandez-Fernandez and Pachano-Arenas, 2008) and robotic (Gundeti et al., 2006; Smith et al., 2009) reconstruction of the ureter in a preureteral vena cava via both the transperitoneal and retroperitoneal approaches in children has been described. Reoperative robotic correction of a missed preureteral cava after pyeloplasty has been described, highlighting the fact that modern imaging may not always permit an accurate diagnosis (Junejo et al., 2018).

Other Anomalies of Position

Several instances of horseshoe kidney have been reported (Cukier et al., 1969; Cendron and Reis, 1972; Heffernan et al., 1978; Taguchi et al., 1986). Anomalies include a variety of left renal anomalies, such as agenesis, hydronephrosis, malrotation, and hypoplasia (Kenawi and Williams, 1976). An obstructing branch of the right spermatic vein and a lumbar vein have mimicked circumcaval ureteral obstruction, as has an anomalous tendon of the iliopsoas muscle (Dreyfuss, 1959; Psihramis, 1987; Guarise et al., 1989).

Preureteral Iliac Artery (Retroiliac Ureter).

A ureter coursing behind the common iliac artery is rare (Corbus et al., 1960; Seitzman and Patton, 1960; Hanna, 1972; Radhkrishnan et al., 1980). Either side can be involved; in two cases, the condition was bilateral (Hanna, 1972; Radhkrishnan et al., 1980). Obstruction occurs at the level of L5 or S1 as the ureter is compressed behind the artery. Coexisting anomalies are common, particularly vasal anomalies (Nguyen et al., 1989; Seitzman and Patton, 1960;

Radhkrishnan et al., 1980).

Like the preureteral cava, the preureteral iliac artery is considered to be of vascular origin without definitive proof. Normally, the primitive ventral root of the umbilical artery is replaced by development of a more dorsal branch between the aorta and the distal umbilical artery. Persistence of the ventral root as the dorsal root fails to form traps the ureter dorsally.

Ureteral or mesonephric duct ectopia is often present (Nguyen et al., 1989). The case of Seitzman and Patton involved an ectopic ureter that emptied, along with the ipsilateral vas deferens, via a persistent common mesonephric duct into the proximal posterior urethra (Seitzman and Patton, 1960). In the case of Radhkrishnan et al., bilateral retroiliac ureters also involved bilateral ectopic termination of the vasa deferentia into the ureters (Radhkrishnan et al., 1980). Iuchtman et al. described ectopic vaginal termination of the involved ureter, with urometrocolpos from an imperforate hymen (Iuchtman et al., 1980).

Taibah et al. reported the unusual finding of left ureteral obstruction from a retrointernal iliac artery ureter in an otherwise normal young woman (Taibah et al., 1987).

Vascular Obstruction of the Distal Ureter.

Obstruction of the distal ureter from uterine, umbilical, obturator, and hypogastric vessels close to the bladder has been described (Campbell, 1936; Young and Kiser, 1965; Scultety and Varga, 1975). However, it is not always clear that vascular impressions on a dilated ureter are the cause of the obstruction. At times, these findings may be an artifact, as when a dilated ureter from an intrinsic obstruction is secondarily compressed against the adjacent vessel. Judging from the paucity of contemporary reports describing this lesion, it is likely that primary terminal ureteral obstruction by vascular lesions is a rare occurrence.

Herniation of the Ureter.

Herniation of the ureter is another extremely rare condition. Dourmashkin reported a series of inguinal, scrotal, and femoral herniations of the ureter (Dourmashkin, 1937). Most of these were paraperitoneal—that is, a loop of herniated ureter extended alongside a peritoneal hernial sac. Only a minority were extraperitoneal (i.e., with no hernial sac present). In paraperitoneal ureteral hernias, the ureteral loop is always medial to the peritoneal sac. Of six scrotal hernias, four did not have peritoneal sacs. When the ureter extended into the scrotum, it was more likely to be dilated, causing upper tract obstruction.

In children, herniated ureters have manifested with hydronephrosis, associated with megaureters and with persistent hydronephrosis after posterior urethral valve ablation (Jewett and Harris, 1953; Powell and Kapila, 1985; Burgu et al., 2009).

Internal hernias of the ureter are even more exceptional. Reports have been published of a sciatic hernia containing a ureter, herniation between the psoas muscle and iliac vessels, and lumbar triangle herniation (Oyen et al., 1987; Witney-Smith et al., 2007; Tsai et al., 2008; Hsu et al., 2010; Page, 1955; Cabello et al., 2008). Ureteral herniation with obstruction has been reported as a rare complication of renal transplantation (Ingber et al., 2007).

Key Points: Preureteral Vena Cava (Circumcaval Ureter, Retrocaval Ureter)

- Preureteral vena cava involves the right ureter, which typically deviates medially behind (dorsal to) the inferior vena cava, winding about and crossing in front of it from a medial to lateral direction, to resume a normal course to the bladder.
- If the subcardinal vein in the lumbar portion fails to atrophy and becomes the primary right-sided vein, the ureter is trapped dorsal to it.
- The preureteral cava may manifest with symptoms of flank or abdominal pain or infection, or the disorder may be discovered incidentally.
- Surgical correction involves ureteral division, with relocation and ureteroureteral or ureteropelvic reanastomosis, usually with excision or bypass of the retrocaval segment, which can be aperistaltic.

Surgery of the Ureter in Children

Ureteropelvic Junction, Megaureter, and Vesicoureteral Reflux

L. Henning Olsen MD, DMSc, Yazan F.H. Rawashdeh MD, PhD

Ureteropelvic Junction Obstruction

Definition

Hydronephrosis in children, defined by an anterior-posterior intrarenal pelvis (AP) diameter of 12 mm (Dhillon, 1998), **differs from that seen later in life and is not necessarily synonymous with true obstruction.** Available diagnostic tools are imprecise, rendering Koff's definition as the only gold standard prognosticator of obstruction. Koff defined obstruction as “any restriction to urinary outflow that if left untreated will lead to progressive kidney damage” (Koff, 1987). Working by this definition, indications for surgery are often amassed retrospectively and at the cost of losing “irrevocably” valuable renal function. So, in an attempt to circumvent use of such diagnostics, numerous guidelines have been published, however, and in the absence of precise diagnostic tools **indications for surgery will always be debatable** (Chertin et al. 2006). The first part of this chapter focuses on open surgical repair of ureteropelvic junction obstruction (UPJO) including retrocaval ureters, mid-ureteral strictures, and UPJO in duplex systems. As there is an evolving interest in minimally invasive procedures such as laparoscopy, retroperitoneoscopy, and robotic procedures, these procedures are also described in detail. The second part of the chapter discusses surgery for vesicoureteral reflux (VUR) and surgery for congenital megaureter.

Clinical Presentation

In many countries, antenatal ultrasound scans are offered at approximately 20 weeks’ gestation. Of the malformations identified, urogenital anomalies are dominant, and of these, dilations in the form of hydronephrosis or hydroureteronephrosis are most common. Postnatal diagnosis is made by ultrasonography, incidentally or in conjunction with the workup for a child presenting with urinary tract infections (UTIs). Febrile infections are often sufficiently treated with antibiotics, with only a minority of patients needing nephrostomy tube diversion in case of concomitant finding of hydronephrosis or hydroureteronephrosis. **Most often, the UPJO in newborns and infants is caused by an *intrinsic* narrowing of the ureteropelvic junction (UPJ) (Fig. 42.1). The typical finding is a narrowed segment of the UPJ with an**

interruption in the development of the circular muscular fibers. This leads to a functional discontinuity of the muscular contractions and ultimately to insufficient emptying of the renal pelvis. **UPJO in childhood and adolescence is often caused by an accessory vessel to the lower pole of the kidney (Fig. 42.2), with the ureter kinking over the lower pole vessel** (Lowe and Marshall 1984) **(*extrinsic)* giving rise to loin pain, nausea, and vomiting.** However, it is unclear whether an intrinsic factor in conjunction with a lower pole vessel is the reason for the symptomatic hydronephrosis (Stephens, 1982). Hydronephrosis is more often seen in boys (Williams and Karlaftis, 1966; Kelalis et al., 1971; Johnston et al., 1977; Olsen et al., 2007), especially in the infant and toddler age groups (Robson et al., 1976; Williams and Kenawi, 1976; Johnston et al., 1977). UPJO predominates on the left side and is bilateral in 10% to 40% (Nixon, 1953; Uson et al., 1968; Robson et al., 1976; Lebowitz and Griscom, 1977; Karnak et al., 2008). There might also be an increased incidence in family members (Cohen et al., 1978).

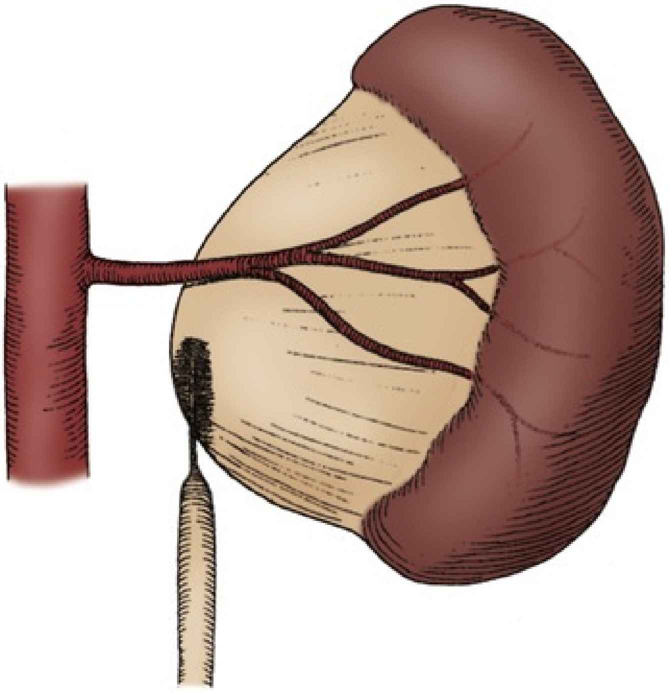

FIG. 42.1 Intrinsic narrowing of upper ureter contributing to ureteropelvic junction obstruction.

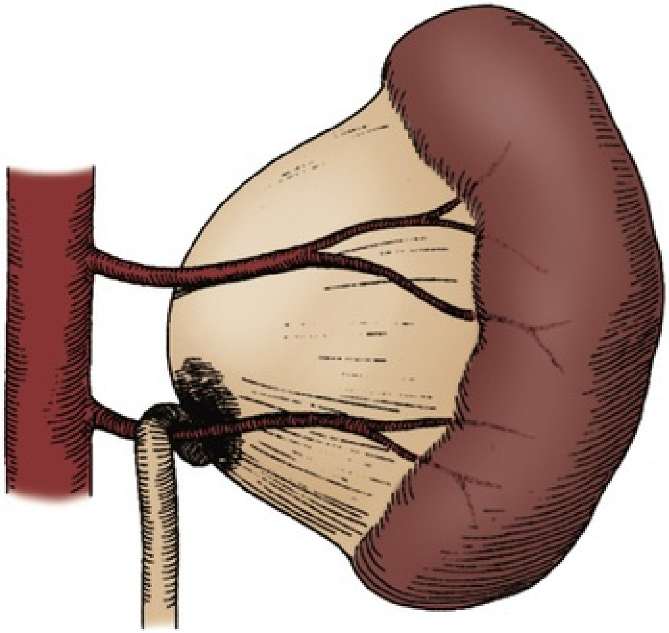

FIG. 42.2 A lower-pole crossing vessel contributes to significant kinking at the ureteropelvic junction and resultant intermittent obstruction. Often, when the ureter is mobilized, no evidence of intrinsic narrowing is found. However, dismembering and moving of the ureter anteriorly to the vessel prevents recurrence of symptoms.

Secondary Ureteropelvic Junction Obstruction

In some cases of high-grade VUR with a torturous dilated ureter, kinking or narrowing of the UPJ can be present. Whether this resolves spontaneously or needs surgical correction of both the VUR and the UPJO is not always clear (Lebowitz and Blickman, 1983; Bomalaski et al., 1997). Because this condition is specific to high-grade reflux, in which surgical correction of the VUR by injectable biomaterials is doubtful, contemplating simultaneous reimplantation and dismembered pyeloplasty is discouraged as there are concerns this may compromise ureteral blood supply. Therefore a conservative approach or operation in two stages is advisable, despite the lack of convincing evidence.

Lower Pole Ureteral Pelvic Junction Obstruction

In uncommon cases of duplex kidneys, a UPJO of the lower moiety is seen (Fig. 42.3) (Privett et al., 1976). In cases of incomplete duplication, a ureteropelvic anastomosis of the upper pole ureter to the lower pole pelvis is possible, either side-to-side or end-to-side. In cases of complete duplication, a standard dismembered pyeloplasty is done, depending on the function of both the upper and lower moiety and the length of the stenosis (Joseph et al., 1989). A nonfunctioning or minimally functioning moiety (i.e., ≤5% to 10% of overall kidney function on nuclear scan) should prompt partial nephrectomy rather than any attempts at repair.

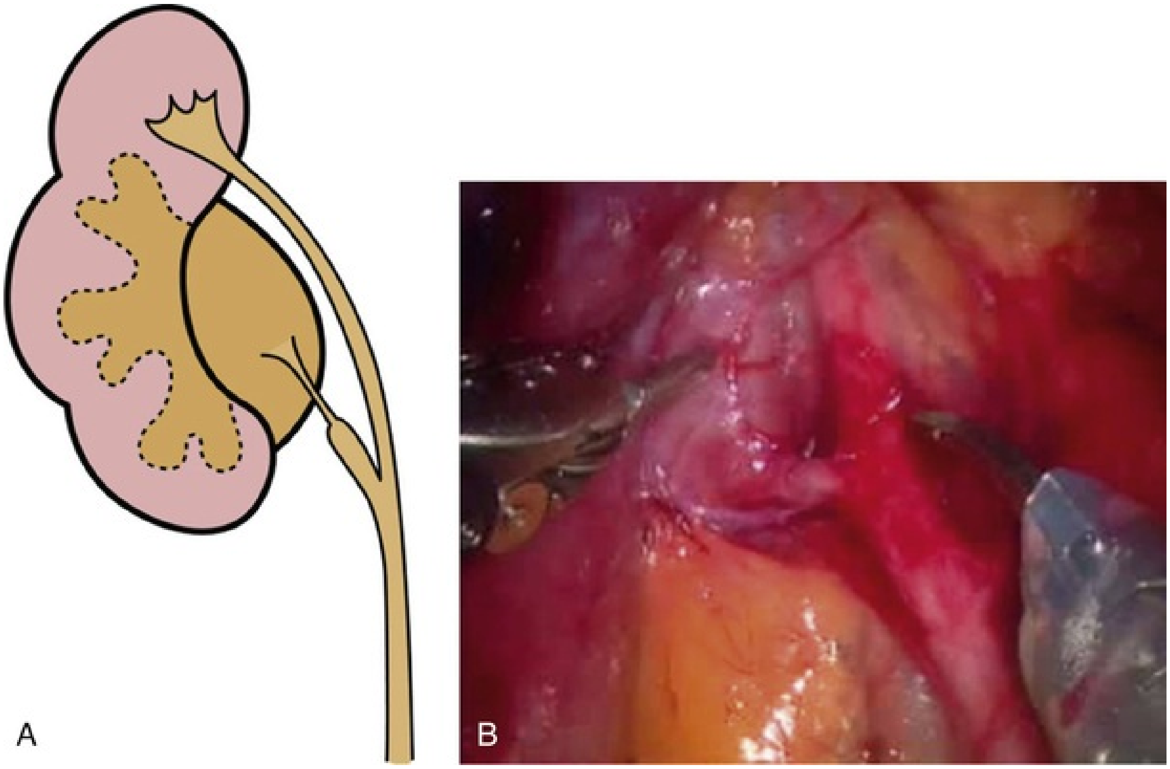

FIG. 42.3 (A and B) Duplex kidney with stenosis of the lower ureteropelvic junction. A V-plasty can resolve the problem.

Associated Anomalies

Congenital renal malformations are commonly seen in association with UPJO. Up to 50% of the affected infants have another urologic abnormality (Uson et al., 1968; Robson et al., 1976; Lebowitz and Griscom, 1977; Lebowitz and Blickman, 1983). Contralateral UPJO is the most common anomaly, seen in 10 % to 40% of cases, followed by renal dysplasia, multicystic dysplastic kidneys, and renal agenesis (Williams and Karlaftis, 1966; Robson et al., 1976; Williams and Kenawi, 1976). Horseshoe kidneys are rare but are in some cases associated with UPJO, both with a genuine stricture or caused by accessory vessels (Glenn, 1959; Blanc et al., 2013; Je et al., 2015). VATER syndrome has also some association with UPJO (Kolon et al., 2000). Furthermore, VUR is seen in up to 40% of children with UPJO, albeit with a high degree of spontaneous resolution (Williams and Kenawi, 1976; Lebowitz and Blickman, 1983; Je et al., 2015).

Surgical Indication

Only approximately one-third of affected children will need surgical intervention (Dhillon, 1998). The widely accepted indications for surgery are an increasing AP diameter on ultrasonography, low or decreasing differential renal function, breakthrough infections while on prophylactic antibiotics, or symptoms such as pain in older infants and children. In infants, UPJO can be a cause of failure to thrive, feeding difficulties, and constipation. However, the majority of cases resolve with time and do not proceed to surgery (Koff, 1998). Hematuria is seen in some cases and is believed to result from disruption or rupture of mucosal vessels in the dilated pelvis (Kelalis et al., 1971; Williams and Kenawi, 1976). UPJO has also been shown to be a rare cause of hypertension most likely caused by renal functional deterioration and activation of the renin-angiotensin axis (Belman et al., 1968; Squitieri et al., 1974; Munoz et al., 1977; Grossman et al., 1981).

Surgical Repair

When indicated, surgical intervention can be performed by open surgery or laparoscopic and robotic-assisted procedures. In infants, open surgery is the preferred procedure because the incision required does not differ significantly from what is necessary for laparoscopic or robotic access. However, the laparoscopic or robotic-assisted route is feasible, and the cosmetic outcome should be superior to the open access (Avery et al., 2015). **There is an ongoing debate on whether minimally invasive procedures should be conducted through the transperitoneal or retroperitoneal routes, even though the majority of pediatric urologists prefer the retroperitoneal approach when performing an open procedure.** However, few proper randomized studies have been published comparing the transabdominal and retroperitoneal laparoscopic routes (Gao et al., 2012; Badawy et al., 2015). The main argument for laparoscopic transperitoneal access is that the procedure is easier, and offers the surgeon familiar anatomic landmarks that assist in orientation. However, ease should not stand alone as an argument for any kind of surgical access. Other variables that need consideration are the potential risk for damage to intra-abdominal organs, postoperative urine leakage, and subsequent prolonged hospital stay, all of which tip the balance toward the retroperitoneal approach (Liu et al., 2017). Despite a longer learning curve for retroperitoneal access, the authors have preferred and advocated the use of retroperitoneoscopic pyeloplasty, as the advantages seem to outweigh many of the potential difficulties encountered during the learning phase (Olsen and Jorgensen, 2004; Olsen, 2006; Olsen et al., 2007; Olsen and Rawashdeh, 2011).

Dismembered Pyeloplasty

Regardless of access, the Anderson-Hynes dismembered pyeloplasty technique is most surgeons’ preferred procedure and the gold standard against which all other interventions are compared. Originally developed for the repair of an obstruction in a retrocaval ureter, the procedure has since gained widespread acceptance as the standard UPJO repair, with a success rate of about 95% (Anderson and Hynes, 1949; Douville and Hollinshead, 1955; Poulsen et al., 1987; MacNeily et al., 1993; Shaul et al., 1994; McAleer and Kaplan, 1999; O'Reilly et al., 2001; Casale et al., 2004). The initial concerns of compromising the blood supply and innervation of the proximal ureter have since been disclaimed (Douville and Hollinshead, 1955). The advantage of dismembering the UPJ is that a lower pole crossing vessel can be preserved, the adynamic part of the ureter excised, and redundant pelvic tissue reduced (Fig. 42.4). In the case of a long dysplastic segment of the upper ureter, complete mobilization of the kidney can bridge the distance between the pelvis and ureter for several centimeters. In addition, a horizontal incision in the lower part of the pelvis can give further length and facilitate tension-free anastomosis (Fig. 42.5). Irrespective of access, the main steps of the Anderson-Hynes dismembered pyeloplasty are as follows (Fig. 42.6): After opening Gerota's fascia, the anterior or posterior aspect of the UPJ is dissected (depending on the access used). The lower pole of the kidney is freed to avoid overlooking an accessory vessel, especially with retroperitoneoscopic access. Electrocautery should be used with caution to minimize damage to the blood supply of both the pelvis and ureter, with preference given to bipolar diathermy. A stay suture can be placed in the pelvis proximal to the anticipated line of dismemberment, and another stay suture can be placed in the ureter at the level of the stenosis. The UPJ is dismembered, and the pelvis is reduced if indicated. A tensely dilated pelvis should be decompressed with a 21-gauge needle before dismembering to avoid excessive pelvic reduction. The ureter is then spatulated along its lateral border, well beyond the dysplastic stenotic segment and carried through adequately into healthy ureteral tissue. At this stage, the stenotic part of the ureter is not removed, as it can serve as a handle that minimizes ureteral tissue manipulation while performing the anastomosis and therefore reduces the risk for mucosal edema. The anastomosis can be completed with interrupted or continuous suturing according to the surgeon's preference. Suture size depends on the prevailing anatomy, but most often a 6-0 or 5-0 absorbable monofilament or polyfilament suture on a round needle is used. Care should be taken at the tip of the *V* at the crotch of the anastomosis, which must be assembled precisely and in a tension-free manner. One should also avoid placing inadvertent excessive tension on the stay sutures while aligning the anastomosis, as this can lead to kinking of the ureter once tension is relieved. Just before completing the anastomosis, the stenotic part of the ureter is removed, and the pelvis is irrigated with saline to avoid blood clots obstructing the ureter. Stenting the anastomosis and the type of stent (either externalized transanastomotic nefro-ureteric or internal pigtail stent) is a matter of choice that differs among surgeons and institutions. In a recent randomized study, Nasser et al. found that stenting with an externalized nefro-ureteric stent reduces complications and length of hospital stay in infants in contrast with no stenting (Nasser et al., 2017). Chu et al. did not find any differences with regard to complications between a pigtail and an externalized stent (Chu et al., 2018). The duration of stenting between 1 to 4 weeks does not seem to affect the outcome (Danuser et al., 2014). The kidney is brought back to its native position, and the anastomosis can be covered with perinephric fat if available. Usually the use of external drainage with a Penrose drain is not indicated.

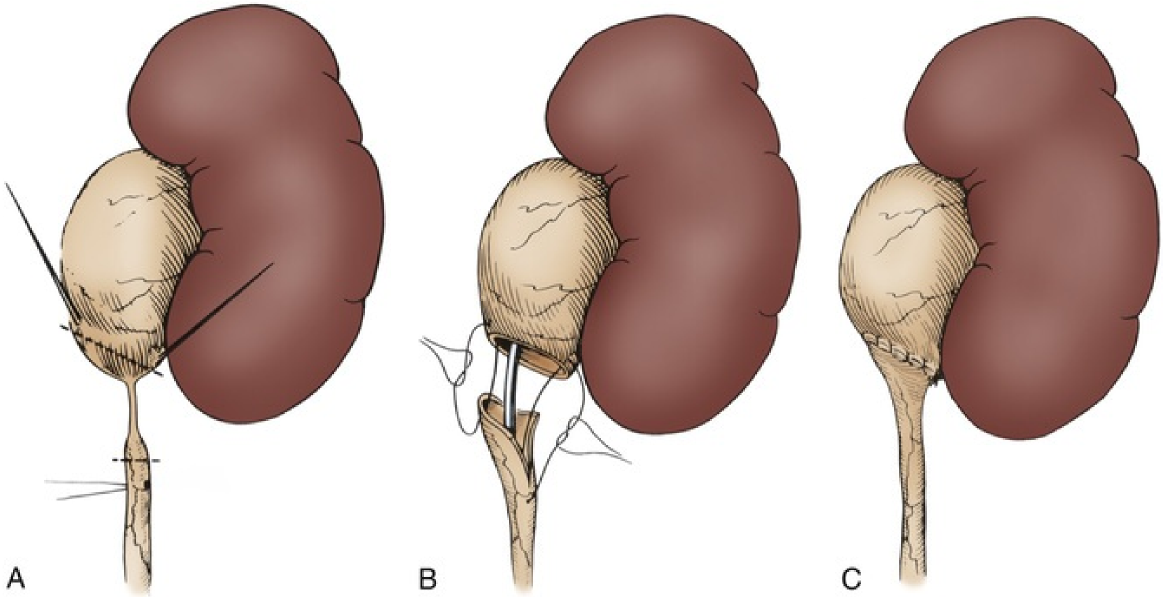

FIG. 42.4 Anderson-Hynes dismembered pyeloplasty. (A) Traction sutures are placed on the medial and lateral aspects of the dependent portion of the renal pelvis in preparation for dismembered pyeloplasty. A traction suture is also placed on the lateral aspect of the proximal ureter below the level of the obstruction. This suture will help maintain proper orientation for the subsequent repair. (B) The ureteropelvic junction is excised. The proximal ureter is spatulated on its lateral aspect. The apex of this lateral, spatulated aspect of the ureter is then brought to the inferior border of the pelvis while the medial side of the ureter is brought to the superior edge of the pelvis. (C) The anastomosis is performed with fine interrupted or running absorbable sutures placed full thickness through the ureteral and renal pelvic walls in a watertight fashion.

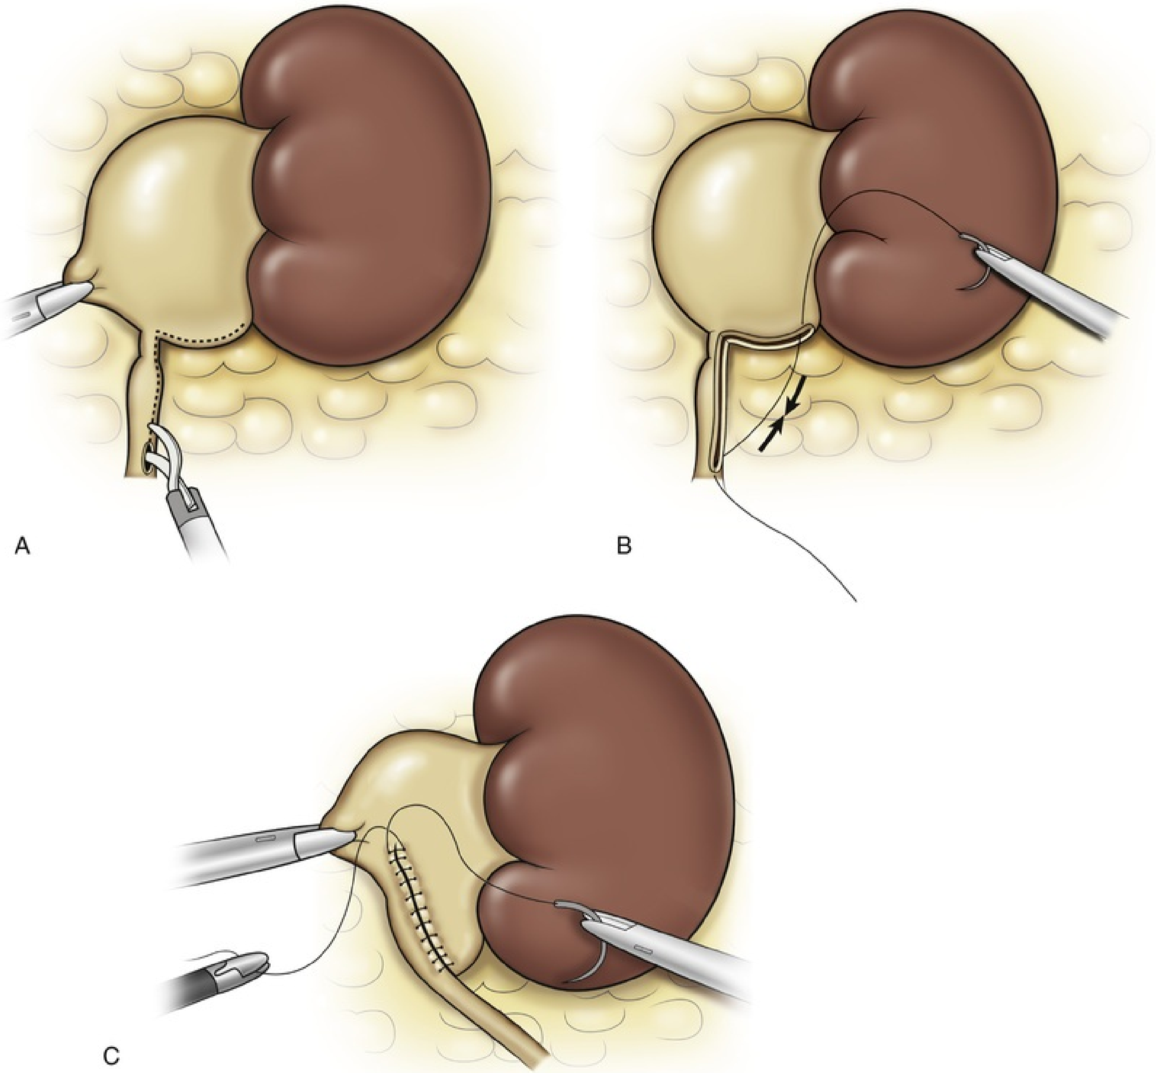

FIG. 42.5 The schematic represents a modified “bypass” pyeloplasty in which a side-to-side anastomosis of the ureter and renal pelvis is performed without transecting the stenotic ureteropelvic junction (UPJ). This allows the new UPJ to be configured within 1 cm of the lower pole parenchyma. It also keeps the ureter oriented by keeping it anchored to the pelvis during reconstruction, encouraging a “no touch” technique.

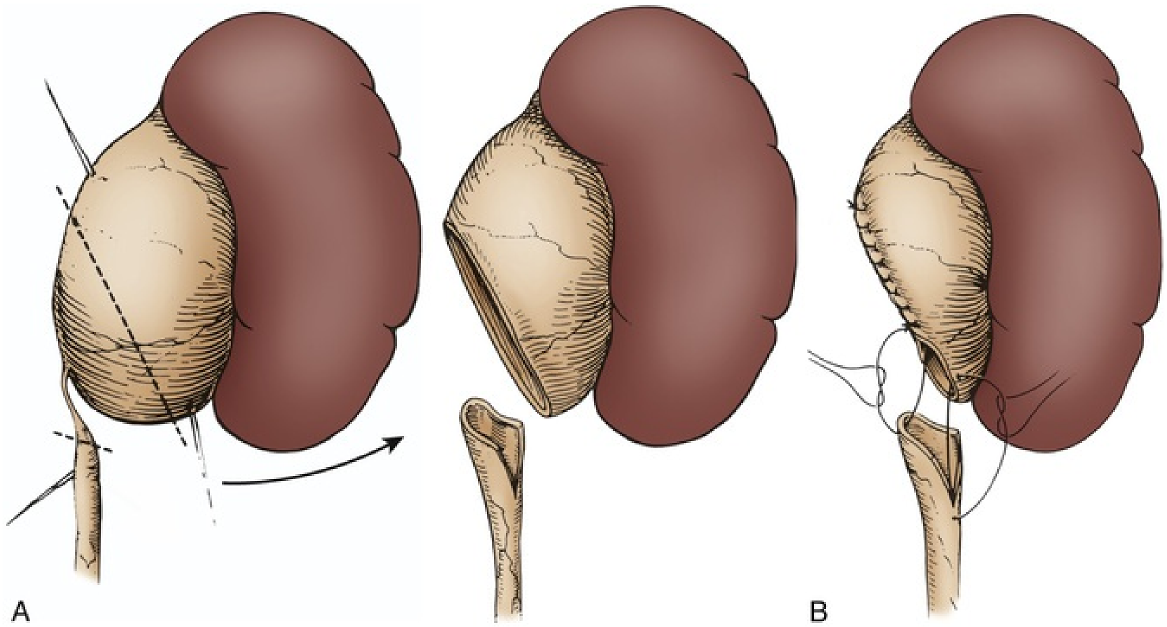

FIG. 42.6 (A) For a large or redundant pelvis, a reduction pyeloplasty is performed by excising the redundant portion between traction sutures. (B) The cephalad aspect of the pelvis is then closed with running absorbable sutures down to the dependent portion. The dependent aspect of the pelvis is anastomosed to the proximal ureter as described in Fig. 42.4.

Nondismembered Pyeloplasty

Several techniques have been described for nondismembered pyeloplasty. In a comparative series of 26 children using the laparoscopic approach, Casale et al. showed that dismembered pyeloplasty gives results superior to those of nondismembered pyeloplasty of the Heineke-Mickulicz fashion (Casale et al., 2004). A feasible alternative is the Foley Y-V plasty, especially in cases with a high insertion of the ureter and no accessory vessels (Fig. 42.7). In a prospective randomized study, Szydełko et al. compared the outcome of Anderson-Hynes pyeloplasty and the Foley Y-V plasty, with success rates of 95% and 86%, respectively, although the difference did not reach statistical significance (Szydełko et al., 2012). A vertical (Fig. 42.8) or spiral flap (Fig. 42.9) technique may be an option in cases of severe hydronephrosis with a long stenotic ureteral segment, which makes tension-free primary anastomosis impossible. The “bypass” pyeloplasty (see Fig. 42.5) might be a feasible alternative, although a systematic review of this technique is not available.

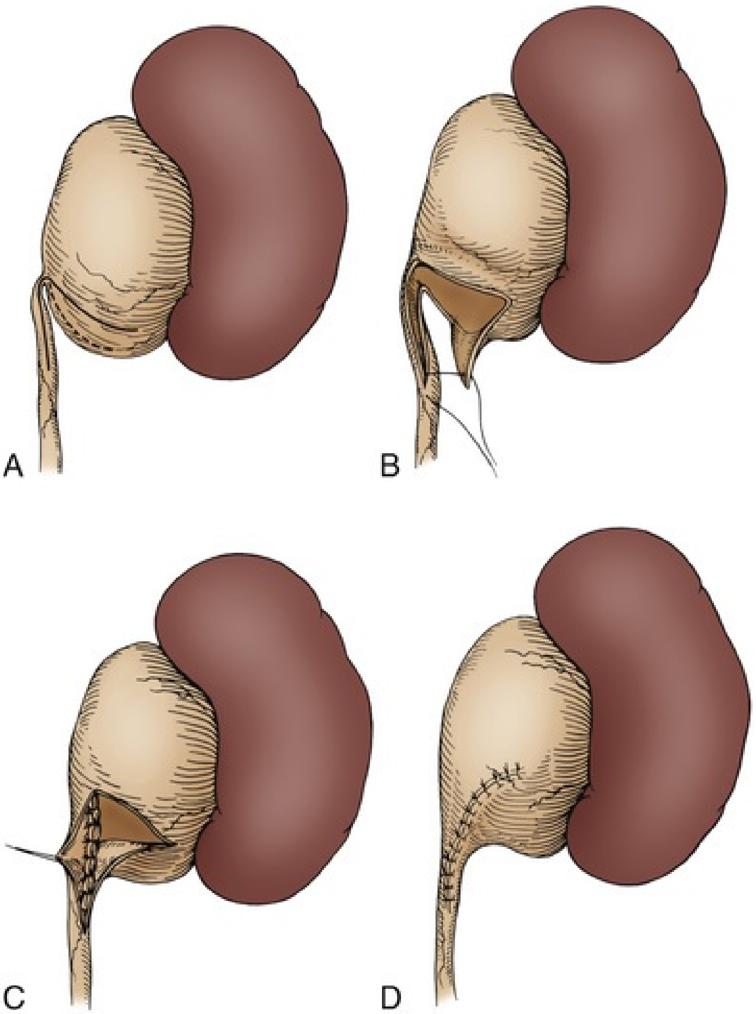

FIG. 42.7 (A) A Foley Y-V plasty is best applied to a ureteropelvic junction obstruction associated with a high insertion of the ureter. The flap is outlined with tissue marker or stay sutures. The base of the V is positioned on the dependent, medial aspect of the renal pelvis and the apex at the ureteropelvic junction. The incision from the apex of the flap, which represents the stem of the Y, is then carried along the lateral aspect of the proximal ureteral wall into an area of normal caliber. (B) The flap is developed with fine scissors. The apex of the pelvic flap is brought to the most inferior aspect of the ureterotomy incision. (C) The posterior walls are approximated using interrupted or running fine absorbable sutures. (D) The anastomosis is completed with approximation of the anterior walls of the pelvic flap and ureterotomy.

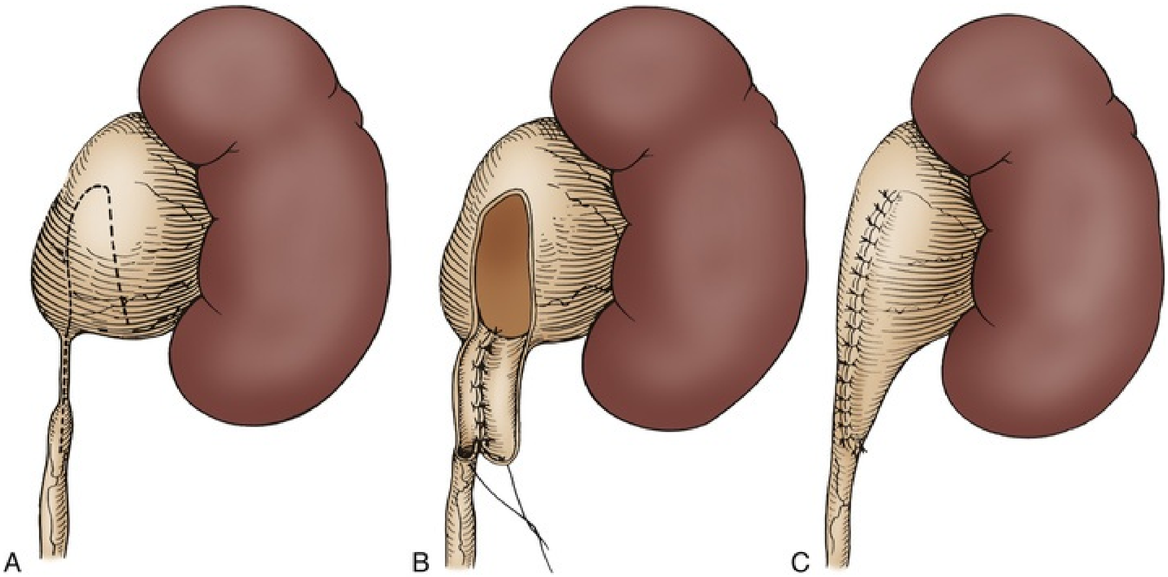

FIG. 42.8 (A) Vertical flap technique may be used when a dependent ureteropelvic junction is situated at the medial margin of a large, box-shaped extrarenal pelvis. In contrast with the spiral flap, the base of the vertical flap is situated more horizontally on the dependent aspect of the renal pelvis, between the ureteropelvic junction and the renal parenchyma. The flap itself is formed by two straight incisions converging from the base vertically up to the apex on either the anterior or posterior aspects of the renal pelvis. As for the spiral flap, the position of the apex determines the length of the flap, which should be a function of the length of proximal ureter to be bridged. The medial incision of the flap is carried down the proximal ureter completely through the strictured area into normal-caliber ureter. (B) The apex of the flap is rotated down to the most inferior aspect of the ureterotomy. (C) The flap is closed by approximating the edges with interrupted or running fine absorbable sutures.

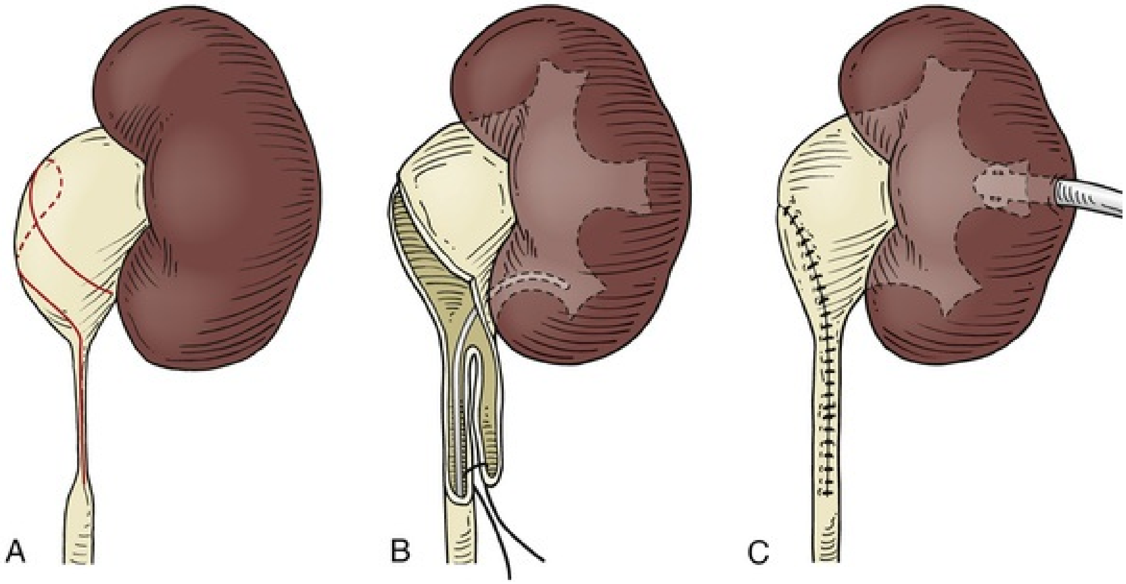

FIG. 42.9 (A) A spiral flap may be indicated for relatively long areas of proximal ureteral obstruction when the ureteropelvic junction is already in a dependent position. The spiral flap is outlined with the base situated obliquely on the dependent aspect of the renal pelvis. The base of the flap is positioned anatomically lateral to the ureteropelvic junction between the ureteral insertion and the renal parenchyma. The flap is spiraled posteriorly to anteriorly, or vice versa. The anatomically medial line of incision is carried down completely through the obstructed proximal ureteral segment into normal-caliber ureter. The site of the apex for the flap is determined by the length of the flap required to bridge the obstruction. The longer the segment of proximal ureteral obstruction, the farther away is the apex because this will make the flap longer. To preserve vascular integrity to the flap, however, the ratio of flap length to width should not exceed 3 to 1. (B) Once the flap is developed, the apex is rotated down to the most inferior aspect of the ureterotomy. (C) The anastomosis is completed, usually over an internal stent, using fine absorbable sutures.

Surgical Approach to Ureteral Pelvic Junction Obstruction

Posterior Lumbotomy

This approach should be reserved for infants and toddlers, because the increasing dorsal musculature with age can make this access difficult if not impossible (Fig. 42.10). In prone position, after a vertical incision is made, the lumbodorsal fascia is incised and retracted laterally. Gerota's fascia is opened, giving direct access to the UPJ. The renal pelvis and the proximal ureter are then stabilized with stay sutures, and the UPJO repair is performed as previously described.

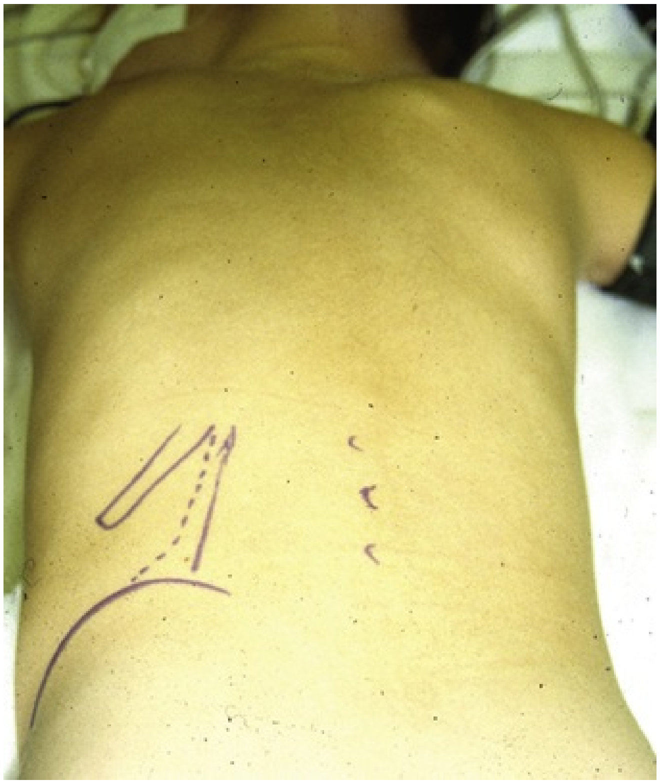

FIG. 42.10 Positioning a patient for left posterior lumbotomy incision. An oblique incision is made from the angle of the 12th rib down to the iliac crest at a point one-third of the distance from the anterior superior iliac spine to the spinal processes.

Flank Approach

In a supine position, the index side is supported by a gel roll. A small transverse incision is made at the level of the tip of the 11th to 12th rib. The fascial and muscle layers are separated in a muscle-splitting fashion. The peritoneum is liberally loosened from the abdominal wall muscles and swept medially, thus giving access to Gerota fascia. The fascia is opened vertically and pushed medially. The UPJ is dissected and stabilized with stay sutures in the pelvis and proximal ureter. The pyeloplasty is then performed as described earlier.

Minimally Invasive Techniques

Endoscopic Approach

The antegrade and retrograde endoscopic approaches to UPJO were popularized in the late 1980s and 1990s with varying results. The reported success rate on long-term follow-up of balloon dilation in patients younger than 18 years of age was 25% (Osther et al., 1998), and the ureteral cutting balloon catheter showed a success rate of 78% in adults, including two patients requiring embolization of a lower pole vessel as a result of gross postoperative hematuria (Kim et al., 1998). Kim et al. recently reported a review of their 25 years of experience with endopyelotomy and found a success rate of 62% in primary UPJO, and the success rate in secondary UPJOs caused by scarring, for example, was as high as 94% (Kim et al., 2012). Antegrade pyelotomy should be reserved for older children and adolescents with moderate hydronephrosis (Figenshau and Clayman, 1998). However, preoperative screening for accessory vessels is required by CT, MRI, or transluminal ultrasonography to avoid vascular injury. Additionally, fluoroscopy is needed during the procedure, which leads to significant radiation exposure, a factor that makes this approach less attractive in pediatrics. **However, endopyelotomy may have a place in the management of failed primary open or laparoscopic procedures (Fig. 42.11) followed by the placement of a double pigtail catheter for 6 weeks. In these cases, the precise anatomy is known from the primary procedure where absence of an accessory vessel is documented. However, patients should be carefully selected and a redo pyeloplasty, either open, laparoscopic, or robotic-assisted, remains the best choice in most cases** (Davis et al., 2016).

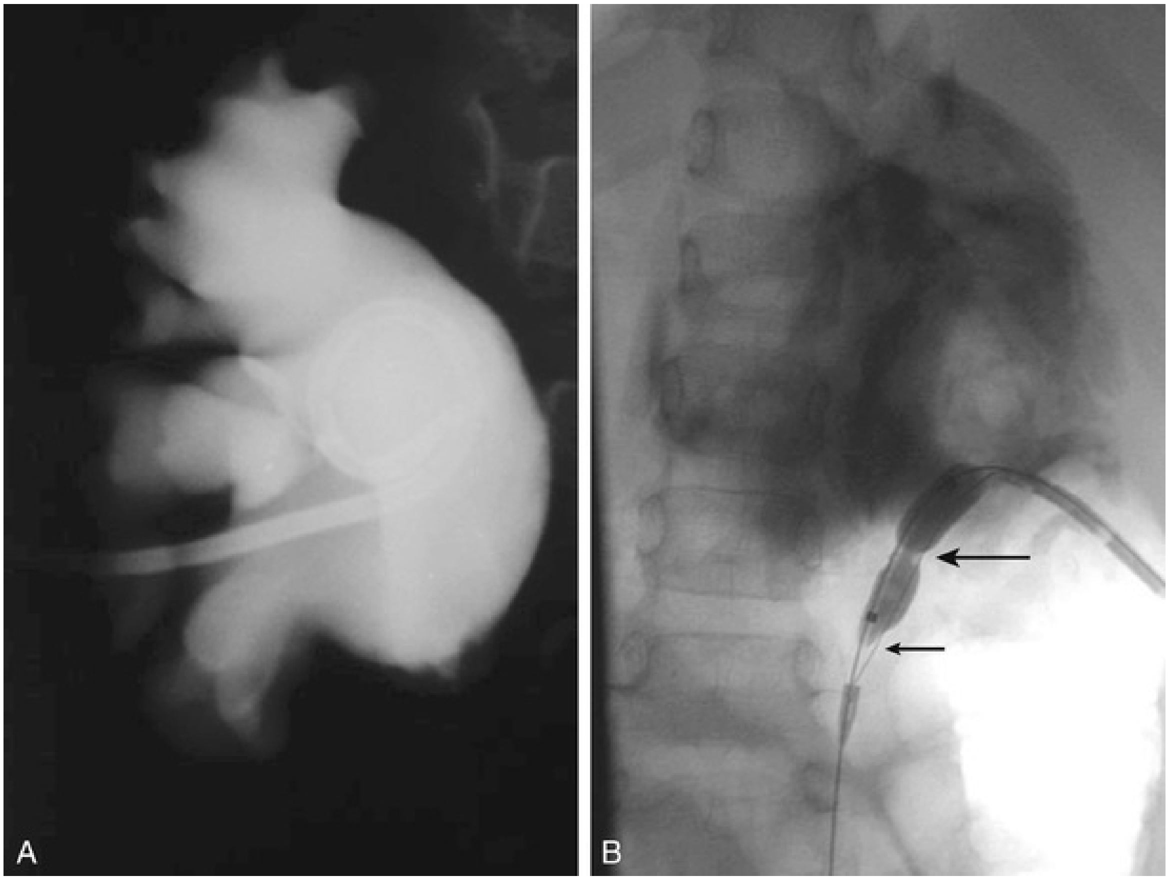

FIG. 42.11 (A) Right antegrade nephrostogram performed 2 months after dismembered pyeloplasty, demonstrating persistent obstruction at the ureteropelvic junction. A nephrostomy tube was placed 2 weeks postsurgery, after which the patient developed flank pain, fever, and *Staphylococcus aureus* urinary tract infection. (B) Acucise balloon is inflated across the ureteropelvic junction narrowing. Note waist present in balloon *(upper arrow)* and cutting wire positioned laterally *(lower arrow).*

Laparoscopic Pyeloplasty

The first cases of laparoscopic pyeloplasty were reported in 1993 (Kavoussi and Peters, 1993). Tan and Roberts reported the first preliminary results of the transabdominal approach, and Yeung et al. described the retroperitoneal approach in infants and children (Tan and Roberts, 1996; Yeung et al., 2001). The evolution of both instruments and video equipment has made the laparoscopic approach widely accepted, and it has become the method of choice at many centers (Metzelder et al., 2006; Sweeney et al., 2011; Blanc et al., 2013). Autorino et al. concluded in a meta-analysis that the laparoscopic approach has a comparable outcome to open surgery, with the robotic technique as an attractive alternative (Autorino et al., 2014).

Transperitoneal or Retroperitoneal Approach.

From a theoretical point of view, the retroperitoneal approach should be safer and is the route of choice in open surgery. However, only a few studies have compared retroperitoneal with transperitoneal access and without noting any significant differences in the outcome and or complications. Abuanz et al. found a higher rate of conversion to open surgery in adults when using the retroperitoneal approach compared with the transabdominal route (Abuanz et al., 2010). This might reflect a more technically challenging procedure in the retroperitoneum. Canon et al. reported a longer operative time for the retroperitoneal approach (Canon et al., 2007a). In a prospective randomized study, Badawy et al. compared the retroperitoneal with the transperitoneal approach and found a significantly shorter operative time for the retroperitoneal approach along with “shorter hospital stay, rapid recovery of intestinal function, and early resumption of oral feeding in favor of the retroperitoneal approach” (Badawy et al., 2015).

Robotic-Assisted Pyeloplasty.

At the beginning of this century, the first publications on robotic pyeloplasty in children emerged (Olsen and Jorgensen, 2004; Kutikov et al., 2006a; Lee et al., 2006). **The transperitoneal approach has gained wide acceptance, but the retroperitoneal approach seems to have attracted fewer proponents, undoubtedly because it is a more technically challenging procedure in children with a confined working space, difficult orientation, and relatively large instruments that need to be maneuvered** (Olsen et al., 2007). Robotic-assisted pyeloplasty has a shorter and more efficient learning curve as compared with laparoscopy, as advanced visualization through three-dimensional vision and the dexterity of the instruments all provide for easier manipulation, precise dissection, and suturing. Barbosa et al. compared open and robotic-assisted pyeloplasty in a larger series and found comparable outcomes but a faster resolution rate in the robotic group (Barbosa et al., 2013). Others have found similar results (Lee et al., 2006; Dangle et al., 2013; Autorino et al., 2014). Peters describes the robotic-assisted transperitoneal technique, and Olsen and Rawashdeh describe the robotic-assisted retroperitoneal technique in detail (Peters, 2011; Olsen and Rawashdeh, 2011).

Technique of Laparoscopic or Robotic-Assisted Pyeloplasty.

With the patient in a 45- to 60-degree flank position, **port placement of the *transperitoneal* approach is shown in Fig. 42.12.** The instrument ports can be placed more medially in cases of large hydronephrosis or in small children/infants. The primary access for the camera port is established using the open Hasson's technique, and instrument ports are placed under direct visual guidance. **On both sides, retrocolic access to the kidney is feasible. However, most surgeons prefer a transmesenteric approach on the left side** (Lee et al., 2006; Gupta, Mukherjee et al., 2009; Sedlacek et al., 2010; Khan et al., 2011; Shadpour et al., 2012) because of shorter operating time, lower morbidity, reduced hospital stay, and no difference in outcome when compared with the retrocolic approach. If the pelvis cannot be identified through the mesocolon, the ureter should be identified and followed to the UPJ while being attentive to the possible presence of any accessory vessel (Peters, 2011). The UPJO can then be stabilized by a stay suture, and surgery is performed as detailed earlier. **Essentially, there is no difference in port placement between a laparoscopic transabdominal or robotic-assisted approach.**

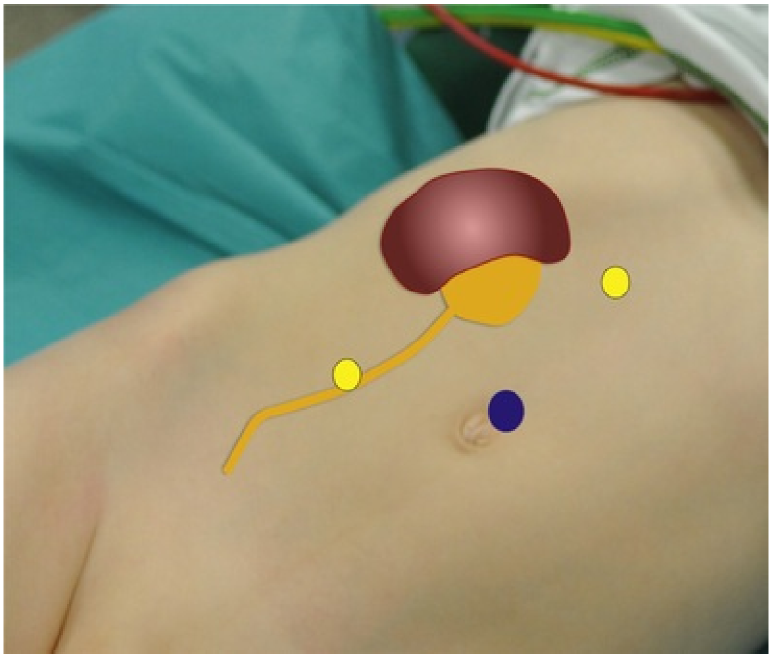

FIG. 42.12 Port placement in transabdominal laparoscopic or robotic-assisted pyeloplasty. *C,* Camera port; *I,* instrument ports.

For the *retroperitoneal* approach, port placement varies in accordance

with the use of laparoscopic or robotic instruments (Fig. 42.13). In both cases, the patient is placed in an 80- to 90-degree flank position. A small gel roll is placed under the contralateral iliac crest, and the upper leg is stretched (Fig. 42.14). The table should not be flexed because this will diminish the AP diameter of the retroperitoneal space. **During the retroperitoneoscopic procedure with standard instruments, the surgeon is positioned behind the patient (dorsally) (see Fig. 42.13A)**, providing better ergonomics (Bonnard et al., 2005). Small children might even be placed diagonally on the table exposing the instruments at a right angle to the surgeon. In the robotic-assisted procedure, the robot is docked from a cranial position and contrary to the case in laparoscopy, camera position is relatively fixed and cannot easily be changed during the procedure. The newest robotic systems are more flexible in this regard. In both cases, a muscle-splitting dissection is carried out at the camera port site, and the lumbodorsal fascia is opened. The retroperitoneal “space” is then developed into 200- to 300-mL working space, depending on the size of the patient. This is done with either a homemade balloon using a 12-Fr catheter with the finger of a latex surgical glove secured to its tip or a commercially available balloon. The latter can be difficult to use in small children because of the large size of these dilators. Additional ports are placed under digital or visual guidance. Use of an extra 5-mm assistance port in the iliac fossa is recommended to facilitate suture delivery and suction during the procedure, as removing and replacing robotic instruments for that same purpose is much more cumbersome and time consuming. After opening Gerota fascia, the UPJ and the pelvis are dissected. A stay suture in the pelvis brought through the abdominal wall or fixed to the psoas muscle provides needed tension and alignment. The pyeloplasty is then performed as described earlier. In case of a UPJO in a horseshoe kidney, the retroperitoneal approach is not advisable because the pelvis is approached from behind. This also applies for the retroperitoneal approach in the rare cases of a retrocaval ureter, at least for the robotic-assisted procedure. Even with standard laparoscopic equipment, retroperitoneal access in these cases is difficult. On the other hand, retroperitoneal access to a UPJO of a lower moiety in a duplex system with the subsequent challenging repair is a perfect case for the robot (see Fig. 42.3).

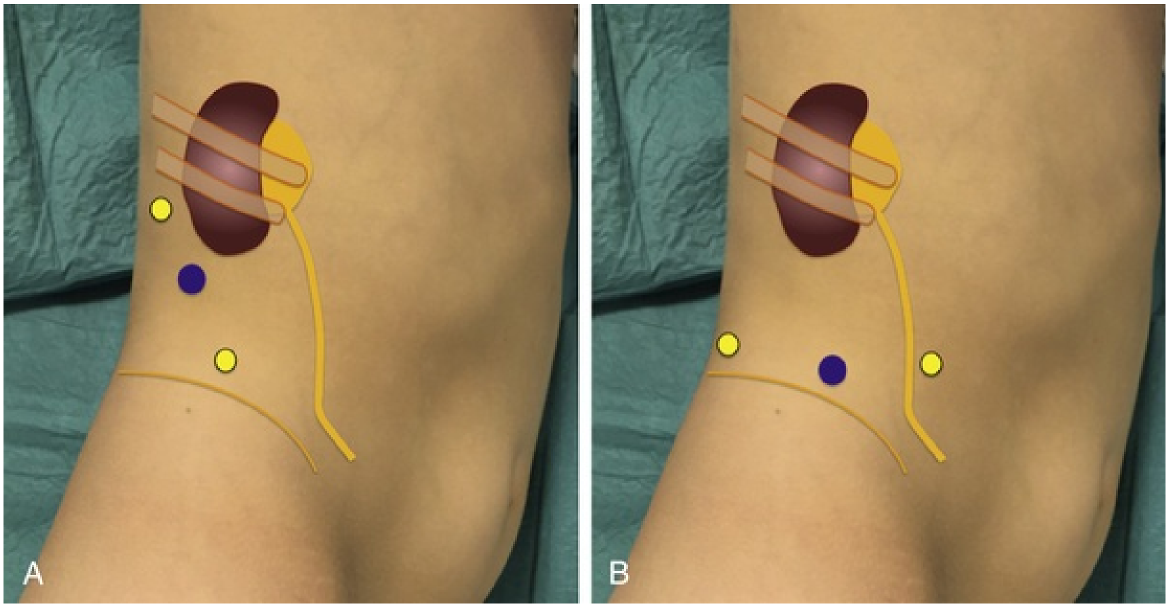

FIG. 42.13 Port placement in retroperitoneal approach. (A) Approach with standard laparoscopic instruments. (B) Approach with robotic assisted instruments. *C,* Camera port. *I,* instrument ports; *a,* assistant port (optional).

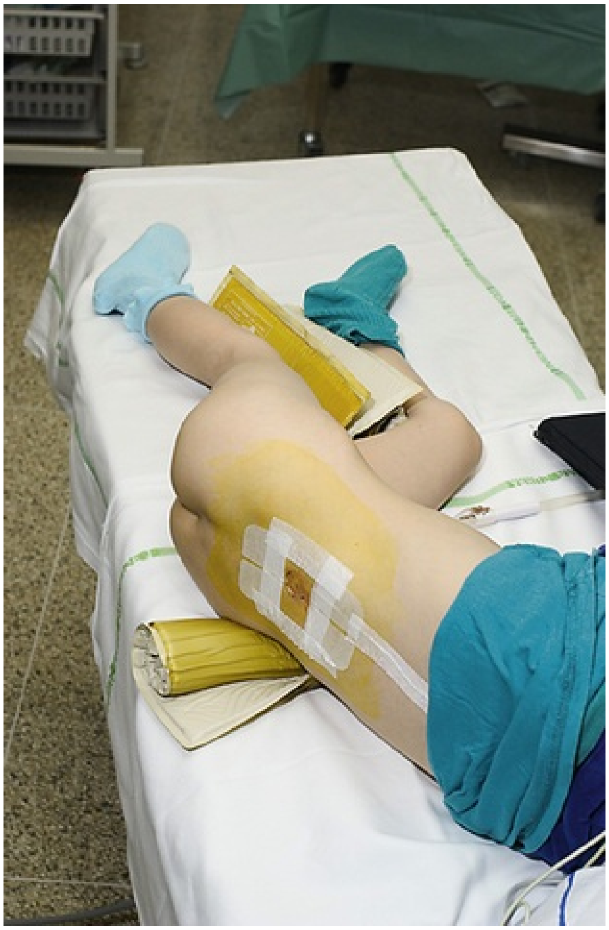

FIG. 42.14 Patient positioning for the retroperitoneal approach. The contralateral iliac crest is supported by a gel role. The table is not flexed to avoid a reduction of the anterior-posterior diameter in the retroperitoneal space. The upper leg is stretched, while the lower leg is bent. This positioning is not advisable for adult patients.

Stones and Congenital Hydronephrosis.

Occasionally pelvic/renal stones are found with congenital hydronephrosis. No matter whether open or laparoscopic/robotic access is used, the treatment of choice is stone removal using a flexible ureteroscope. Alternatively, a flexible cystoscope can be used. The scope can be brought in through either a laparoscopic or robotic port. Standard techniques for stone removal are used as described elsewhere in this book.

Vascular Hitch.

Originally described by Hellstrøm and Vahlquist, the vascular hitch technique (Fig. 42.15) has regained acceptance among laparoscopic surgeons, in part because it is easier to perform than pyeloplasty (Hellstrom and Vahlquist, 1951; Sakoda et al., 2011). However, the technique is only feasible in cases of an anterior lower pole accessory vessel without any intrinsic obstruction of the UPJ. Gundeti et al. conclude that **the vascular hitch should be reserved for cases with “moderate hydronephrosis, no calyceal dilation, a well-preserved cortex, poor renal drainage with preserved split function, and lower pole crossing vessels. Intraoperative criteria included a normal ureter and UPJ with peristalsis”** (Gundeti et al., 2008). Long-term results are limited (Gundeti et al. 2008; Schneider et al., 2013). However, Madec et al. found outcome results in a long-term follow-up comparable to those of dismembered pyeloplasty (Madec et al., 2016). The concern that embedding the lower pole vessels in pelvic tissue gives rise to hypertension has so far not been observed.

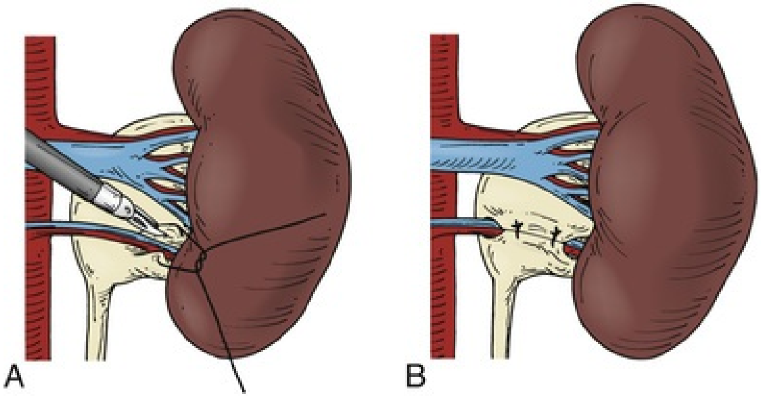

FIG. 42.15 Vascular hitch in cases with crossing vessels and without intrinsic obstruction of the ureteropelvic junction. (A) After removal of all adherences between the ureteropelvic junction and the vessel, the latter is moved cranially on the pelvis and then embedded into pelvic tissue with nonresorbable sutures (B).

Stenting

Most surgeons prefer stenting the UPJ, both in open and minimally invasive surgery (Austin et al., 2000). This decreases the risk for leakage from the anastomosis and subsequent urinoma formation or, if the transperitoneal route is chosen, bowel paralysis caused by urinary ascites. Stentless anastomoses have been advocated by some authors (Liss et al., 2013). This mandates extra careful tissue handling to avoid edema and subsequent obstruction and leakage from the reconstructed UPJ in the postoperative period. Interestingly, Anderson and

Hynes note in their original paper on the dismembered pyeloplasty that; “so-called splinting of any anastomosis is not only unnecessary but is against all the principles of plastic procedure” (Anderson and Hynes, 1949). **Stenting with a double pigtail catheter in children consigns the patient to another anesthesia for stent removal and adds significant time to the procedure when done retrograde in connection with the pyeloplasty.** Use of a stent with an extraction string and placed retrograde can be a feasible alternative. Antegrade intraoperative stenting with a double pigtail catheter can also pose difficulty in passing the ureterovesical junction (UVJ), which can be quite narrow in small infants. For purposes of confirming stent position in the bladder, instillation of methylene blue into the bladder has been advocated. Retrograde stenting immediately before the procedure might make the anastomosis more difficult, and if done days to weeks before surgery (e.g., when emergent diversion is necessary because of obstruction), anastomosis may become more challenging because of local tissue inflammation caused by the catheter traversing the UPJ. It is the authors’ experience to divert with a nephrostomy tube the rare patient with hydronephrosis who needs emergent diversion in close temporal proximity to definitive surgery, as the inflammation caused by a nephrostomy is less severe at the UPJ.

The authors prefer using a transanastomotic nephro-ureteric tube, the so-called “BLUE stent” (Salle Intraoperative Pyeloplasty Stent Set, Cook Medical, Bloomington, IN) (Helmy et al., 2011), **brought out through the renal parenchyma through a middle calyx or directly through the upper part of the anastomosis and the lateral abdominal wall (Fig. 42.16).** This externalized stent is kept open for 12 to 48 hours after which it is knotted and kept in situ for 7 to 14 days and simply pulled out without the need for anesthesia. In cases of obstruction, infection, or postoperative pain, the knot is released and the transanastomotic nephro-ureteric tube drains the system, acting as a nephrostomy tube.

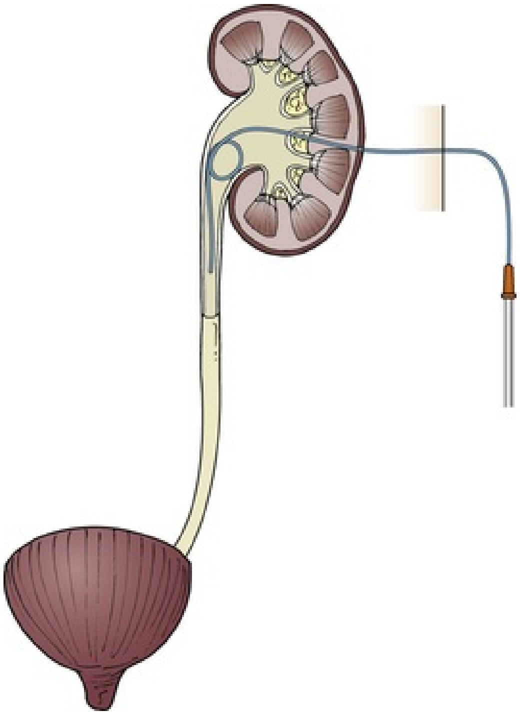

FIG. 42.16 Transanastomotic ureteropyelostomy “Blue Stent.” The lower coil is removed, and the upper end is brought out to the skin, either through the anastomosis or the renal parenchyma. The stent is left open for 24 to 48 hours and then knotted. It can easily be removed after 7 to 14 days without the need for anesthesia.

It is customary to leave the bladder drained by a Foley catheter for up to 24 to 48 hours postoperatively. Although dogmatic and not based on hard evidence, it makes perfect sense when the anastomosis is stented by a double pigtail catheter as VUR will be present transferring bladder pressure unhindered to the renal pelvis. It is however unnecessary when using an externalized transanastomotic nephro-ureteric stent as the lower end of the stent is cut short before placement and does not traverse the UVJ.

Outcome and Complications

In general, pyeloplasty is a safe procedure with few complications and a high success rate between 90% and 100% (Poulsen et al., 1987; O'Reilly, 1989; Macneily et al., 1993; Shaul et al., 1994, Salem et al., 1995; Ragan et al., 1999; Austin et al., 2000; Houben et al., 2000; Casale et al., 2004; Bonnard et al., 2005; Peters, 2011; Autorino et al., 2014). However, the definition of “success” is wide ranging and covers everything from cessation of symptoms to improvement or at least stability of function of the affected kidney, to decreasing

AP diameter of the hydronephrosis on ultrasonography, and more rigidly failure as the need for reoperation or reintervention. This makes the comparison among different outcome studies difficult if not impossible.

Perioperative complications include bleeding from ureteral or pelvic vessels, which can be handled preferably by bipolar diathermy in most cases. Bleeding is the most commonly reported reason for conversion in minimally invasive procedures, followed by lack of progression or difficulties dissecting the UPJ. Postoperatively, infection, pain, and increasing dilation might be early signs of a failed reconstruction (Lindgren et al., 2012). However, blood clots and edema may be the cause and will usually resolve within a few days but may require temporary diversion by a nephrostomy tube. In the long term, decreasing kidney function and increasing dilation may indicate the need for further intervention, initially by balloon dilation/incision of the stenotic UPJ (see Fig. 42.11) and stenting for 4 to 6 weeks, but may ultimately require a redo pyelopasty. In such cases, retroperitoneal access can be cumbersome as a result of scarring, and a transperitoneal approach is preferred. If scarring of the ureter is severe and mobilization of the kidney and ureter does not allow for an appropriate length to perform a tension-free anastomosis, a ureterocalicostomy should be considered. This can be done openly or with a laparoscopic or robotic-assisted procedure (Fig. 42.17) (Davis et al., 2016).

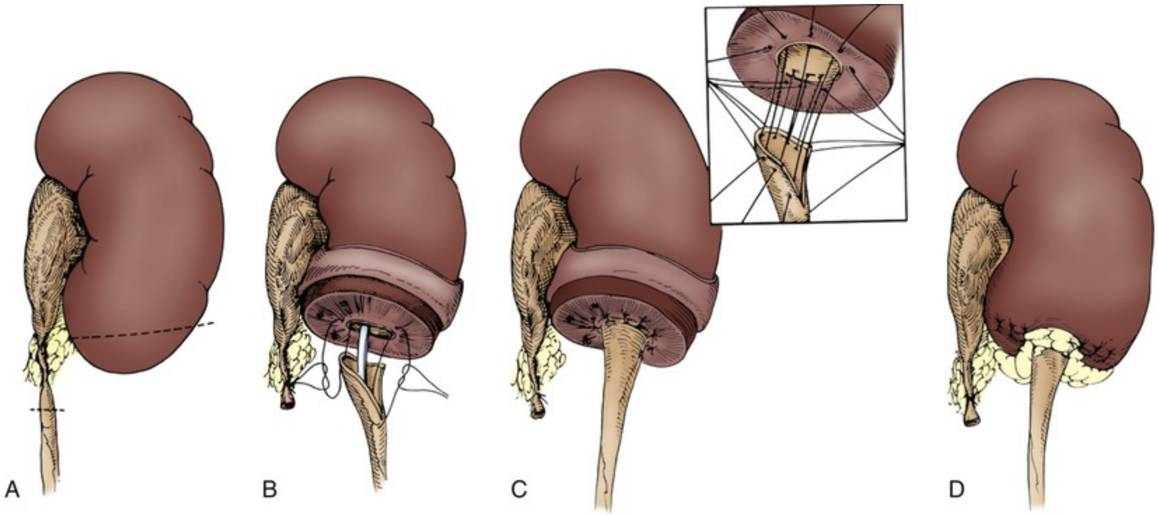

FIG. 42.17 Ureterocalicostomy. (A) The ureter is identified in the retroperitoneum and dissected proximally as far as possible. The kidney is mobilized as much as necessary to gain access to the lower pole and to subsequently perform the anastomosis without tension. A lower pole

nephrectomy is performed, removing as much parenchyma as necessary to widely expose a dilated lower pole calyx. (B) The proximal ureter is spatulated laterally. The anastomosis should subsequently be performed over an internal stent and consideration given to leaving a nephrostomy tube. The initial suture is placed at the apex of the ureteral spatulation and the lateral wall of the calyx, with another suture placed 180 degrees from that. (C) The anastomosis is completed in an open fashion, placing each suture circumferentially but not securing them until the anastomosis has been completed. (D) The renal capsule is closed over the cut surface of the parenchyma whenever possible. However, the capsule should not be closed close to the anastomosis itself because this may compromise the lumen by extrinsic compression. Instead, the anastomosis should be protected with a graft of perinephric fat or with a peritoneal or an omental flap.

Key Points: Pyeloplasty

- UPJO is typically caused by either an intrinsic narrowing in which the ureteral segment has an interruption in the development of the circular musculature of the UPJ; an alteration in collagen fibers in and around the muscular cells; or an extrinsic obstruction that is seen in association with aberrant, accessory, or an early branching lower pole vessel that passes anteriorly to the UPJ or proximal ureter and contributes to mechanical obstruction.
- Congenital renal malformations can be commonly seen in association with a UPJ, with a contralateral UPJO being the most common anomaly, followed by renal dysplasia and multicystic dysplastic kidneys.
- The surgical procedure favored in the repair of a UPJO is the dismembered pyeloplasty, which has been shown to be effective because of its broad applicability, means of allowing excision of the pathologic segment in question, and facilitation of a reduction pyeloplasty when necessary.
- Laparoscopic pyeloplasties provide excellent visualization of the anatomy, enhance cosmesis, and duplicate the results of open pyeloplasties with short-term follow-up. The technical challenges of this approach have been facilitated by the use of a robotic-assisted procedure that improves the anastomotic repair.
- Pyeloplasty complications include prolonged urinary drainage postoperatively, lack of improvement in renal function or improvement in

washout, and, occasionally, worsening hydronephrosis and diminished renal function postoperatively. Such a situation may lend itself to a repair using endoscopic procedures or preferably a repeat dismembered pyeloplasty.

Ureteral Strictures

Congenital ureteral strictures are rare anomalies that have been described causing hydroureteronephrosis. Dilation is identified antenatally but because of their extreme rarity, these patients are usually misdiagnosed as having hydronephrosis or megaureter. Postnatal diagnostics with ultrasonography, MRI, and retrograde pyelography subsequently confirm the diagnosis as being the result of usually a mid-ureteral stricture. Management entails excision of the stenotic ureteral segment and reanastomosis by ureteroureterostomy; excised segments range in length from 1 to 3 cm and are histologically characterized by increased collagen deposition and muscular hypertrophy (Hwang et al., 2005; Brugnara et al., 2007).

Ureteral Polyps

Ureteral polyps are another rare anomaly that may lead to obstruction and dilation. The polyps are most frequently seen in the upper third of the ureter and usually lead to UPJO. They are more common in males and on the left side, can be single or multiple, and can reach several centimeters in diameter. Although they may cause antenatal dilation, they tend to present symptomatically with pain and hematuria later in childhood because of their slow growth and benign nature. Diagnosis can be made by ultrasonography, contrast-based CT scan, and MR urography. Confirmation is usually attained by retrograde pyelography or ureteroscopy. Management options include endoscopic polypectomy, dismembered pyeloplasty with resection of afflicted part of the ureter when polyps are near the UPJ, or ureteral resection and ureteroureterostomy by open and even laparoscopic or robotic surgery. Histologically, they are classified as fibroepithelial benign polyps (Kanamori et al., 2010; Bian et al., 2011; Shive et al., 2012; Li et al., 2015; Osbun et al., 2016).

Vesicoureteric Reflux

Definition and Clinical Presentation

As discussed in Chapter 29, **VUR represents the abnormal retrograde flow of urine from the bladder to the upper urinary tract**. When symptomatic, VUR can give rise to UTIs, pyelonephritic scars, and, at worst, end-stage renal disease. High-grade VUR may also lead to voiding dysfunction, although the exact mechanism is unclear in that there are conflicting interpretations as to whether VUR causes voiding dysfunction or vice versa (Lackgren et al., 2007). **Surgical management of VUR aims at creating one-way, nonobstructed, antegrade flow of urine through the ureter into the bladder by reimplanting the ureter into the bladder in an antirefluxing fashion**. A multitude of surgical procedures and their laparoscopic counterparts have been described. Additionally, minimally invasive endoscopic procedures are also widely in use.

Surgical Management

Key Points: Surgical Principles of Vesicoureteral Reflux Correction

- Excluding causes of secondary reflux.
- Gentle handling of the ureter upon dissection to preserve blood supply and minimize tissue injury.
- Gentle handling of the bladder to minimize postoperative bladder symptoms such as hematuria and bladder spasms.
- Adequate mobilization of the ureter to allow for tension-free anastomosis.
- Establishing an adequate length-to-diameter ratio of 5 : 1 when reimplanting the ureter (Paquin, 1959).
- Maintaining a straight course for the reimplanted ureter, with consideration taken in regard to the distensibility of the bladder and its potential for causing angulations and kinks at either extreme of bladder filling.

The surgical procedures can be classified according to the access and approach used to mobilize the ureter and according to the position of the created submucosal tunnel in relation to the original hiatus of the ureteric orifice. Thus the procedure can be laparoscopic or open, intravesical or extravesical, and the tunnel can be infrahiatal or suprahiatal.

For open surgical procedures, patients are placed in the supine position with slightly abducted hips, and the lower abdomen is raised by placing an appropriate sized gel pad behind the level of the sacrum to facilitate exposure. All pressure points are appropriately padded. The abdomen and perineum are prepped and draped to include the genitalia in the prepared field to allow for sterile urethral catheterization. Prophylactic intravenous antibiotics are given in most cases.

Incision

A Pfannenstiel incision is made along a skin crease 2 cm above the symphysis pubis extending to the edges of the underlying rectus muscles (Fig. 42.18A). The anterior rectus fascia is opened transversely and lifted off the recti to the level of the symphysis pubis inferiorly and to just below the umbilicus superiorly. The rectus abdominis muscles are separated in the midline vertically along the linea alba by blunt dissection, thereby exposing the perivesical space. Alternatively, and in redo cases a vertical lower abdominal incision may be preferable because it allows for more extensive cranial mobilization of the ureters. A moderately filled bladder allows for easier identification and mobilization of the bladder.

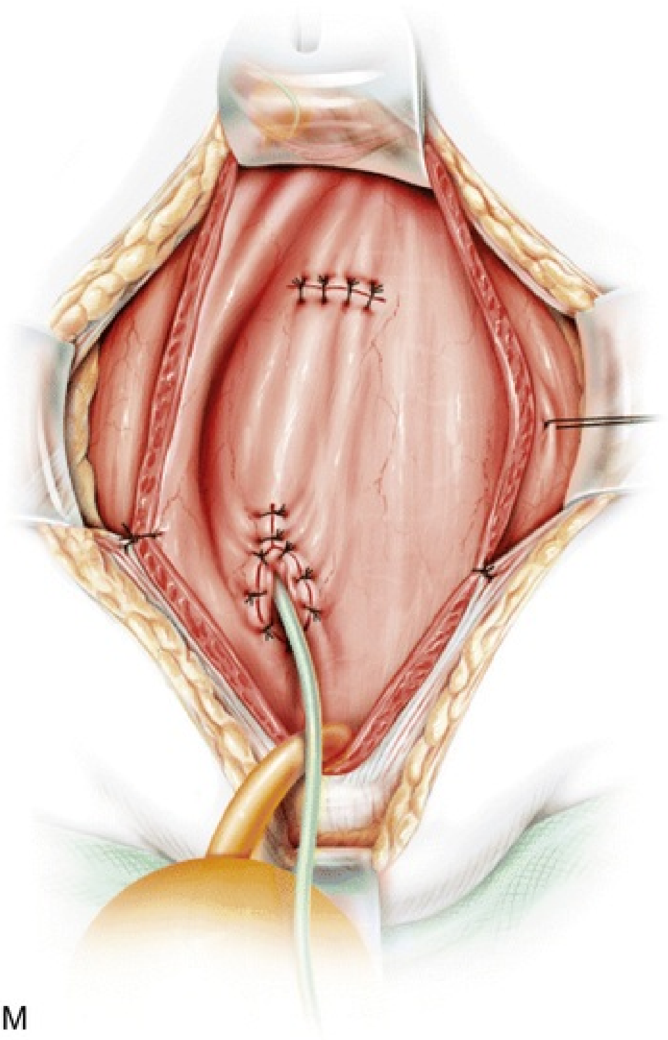

FIG. 42.18 Politano-Leadbetter reimplantation. The bladder is approached extraperitoneally (A) through a Pfannenstiel incision and opened vertically (B) between stay sutures. The refluxing ureteral orifice (C) is identified and cannulated with a 5-Fr baby feeding tube, which is fixed to the ureter with a stay suture that allows handling and traction. The ureter is now mobilized into the bladder (D) by dividing intravesical and extravesical attachments using tenotomy scissors and bipolar diathermy. The superior lip of the original hiatus is retracted with a Langenbeck (E) to sweep off peritoneal attachments and structures from the posterior aspect of the bladder, under direct vision in a superiomedial direction toward the planned neo-hiatus. A right-angled clamp can then be advanced toward the neo-hiatus, incised upon, and dilated appropriately, and a suture is passed from the new to the original hiatus extravesically (F and G). Using the suture as a guide trail, the ureter is now guided out of the bladder and pulled in through the neo-hiatus (H and I). A submucosal tunnel of adequate width is created from the neo-hiatus to the original hiatus, which is closed using 4-0 monofilament absorbable sutures, and the ureter is pulled through the tunnel and shortened appropriately. The ureter is hitched to the detrusor with a 5-0 monofilament absorbable suture at the 6 o'clock

position, and the mucosa is adapted circumferentially to the bladder mucosa in the new position with 6-0 interrupted monofilament absorbable sutures. The mucosal defect at the neo-hiatus is closed with 5-0 absorbable monofilament sutures (J to M).

Intravesical Procedures

When the bladder is identified, the peritoneum is gently swept off the dome. The bladder is opened vertically in the midline between stay sutures, the incision extends to within 2 cm of the bladder neck, and enough of the bladder dome convexity is left, as this allows for packing the bladder dome with saline-soaked surgical gauze, which aids in retraction and presentation of the trigone area (see Fig. 42.18B). The surgical incision is best kept open by using a Denis Brown ring retractor with the blades placed so they retract the bellies of the rectus abdominis muscles laterally on both sides and an additional blade placed cranially within the bladder exerting gentle countertraction on the gauze-packed bladder dome. The lateral bladder walls are retracted laterally by the pull of stay sutures, thereby minimizing trauma incurred by retractor blades directly applied to the friable mucosal lining of the bladder. The ureteric orifice is now cannulated with an appropriately sized baby feeding tube, usually a 5-Fr catheter, which, in turn, is secured to the ureter at its mucosal lip in the bladder with a 5-0 monofilament absorbable suture. The stay suture acts as a handle for traction and aids in dissecting and mobilizing the ureter (see Fig. 42.18C). A circumscribing incision is then made 1 to 2 mm from the orifice using fine-needle–point cautery on low wattage. By applying gentle traction on the stay suture, the ureter can then be mobilized into the bladder by dividing its intravesical and extravesical attachments with tenotomy scissors and bipolar diathermy. **Care must be taken to preserve the blood supply of the distal ureter by confining dissection to the right plane circumferentially**. A narrow retractor (e.g., Langenbeck) can then be introduced at the 12 o'clock position to expose the peritoneal reflection attached to the ureter, which can be gently swept off using a pledget. At this point, the ureter is released and can be mobilized fully into the bladder and will reach the contralateral bladder wall without tension. Depending on the surgeon's preference, experience, and patient in question, the choice of submucosal tunnel is now decided on (see Fig. 42.18D–E).

Politano-Leadbetter Technique

Originally described by Politano and Leadbetter in 1958, this suprahiatal procedure aims at creating a vertical submucosal tunnel from a new hiatus created superiomedial in a straight line down to the native hiatus (Politano and Leadbetter, 1958). The technique is useful in cases of high-grade VUR in which a long submucosal tunnel is needed.

Once the ureter is mobilized within the bladder, an appropriate site for the new hiatus superiomedially is identified and a blunt right-angled clamp is carefully passed through the original hiatus. The clamp is probed toward the new planned hiatus while taking care to sweep off the peritoneal attachments from the posterior aspect of the bladder. Once the clamp is in position and can be felt digitally from inside the bladder, the clamp's right angle is pushed inward opened slightly and incised upon, thereby creating the new hiatus that now can be widened appropriately. **In this step, care must be taken not to injure the bowel, vas deferens, or vagina. The inexperienced surgeon is therefore advised to retract the superior lip of the original hiatus to sweep off the structures under direct vision**. A 3-0 suture can then be passed from the new to the original hiatus extravesically; this will act as a guide rail for the ureter that can then be guided out of the bladder and pulled back in through the new hiatus using the guide suture. The detrusor defect at the original hiatus is closed using 4-0 monofilament absorbable sutures, and a submucosal tunnel is created from the new location to the location of the original hiatus, which is capacious enough to accommodate the ureter without causing constriction. The ureter is then pulled through, shortened adequately to the length of the tunnel, and may be spatulated. The ureter is hitched to the detrusor with a 5-0 monofilament absorbable suture at the 6 o'clock position, and the mucosa is adapted circumferentially to the bladder mucosa in the new position with 6-0 interrupted monofilament absorbable sutures. The mucosal defect at the neo-hiatus is closed with 5-0 monofilament absorbable sutures, and the bladder wall is then closed in one layer using 4-0 monofilament absorbable sutures and decompressed with a Foley catheter for 1 to 3 days. Bladder closure in two layers allows for shorter catheter drainage times. Ureteral stents are only left in complex cases (see Fig. 42.18F–M).

Glenn-Anderson Technique

This technique was described by Glenn and Anderson in 1967 (Glenn and Anderson, 1967). The ureter is mobilized intravesically as mentioned earlier, but the submucosal tunnel is created infrahiatally in the direction of the bladder neck (Fig. 42.19). **A clear advantage over the Politano-Leadbetter operation is the fact that the course of the reimplanted ureter is less liable to angulation and kinking,** whereby obstruction is avoided. The length of the tunnel is however limited by the distance to the bladder neck. As with the other procedures, the outcomes of this technique have been excellent, with reported success rates of up to 98% (Gonzales et al., 1972).

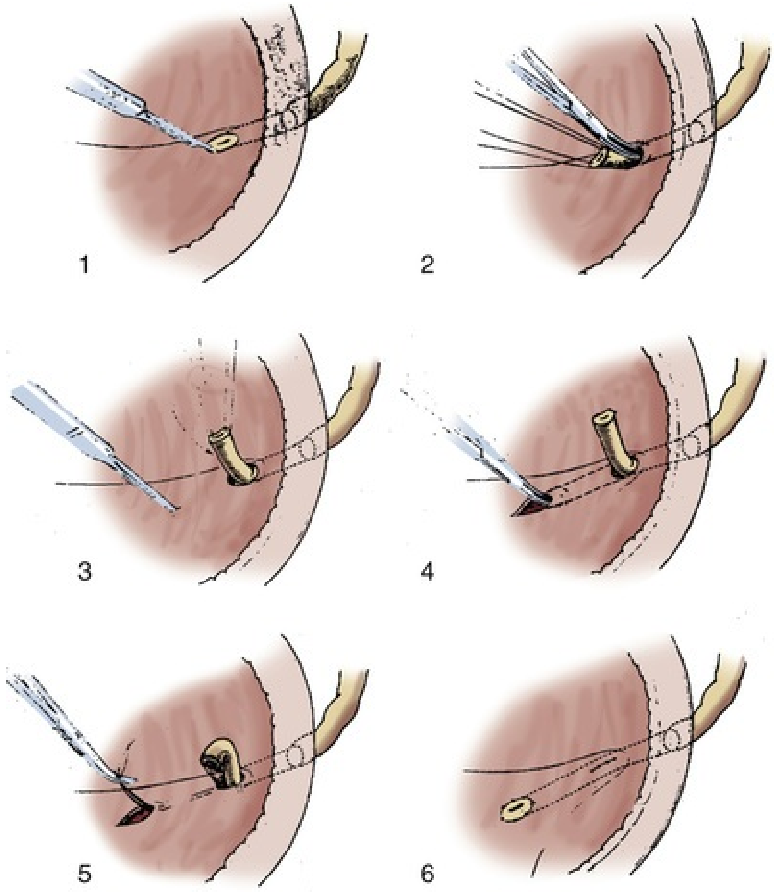

FIG. 42.19 Glenn-Anderson Reimplantation; The ureter is mobilized and advanced beneath a new submucosal tunnel.

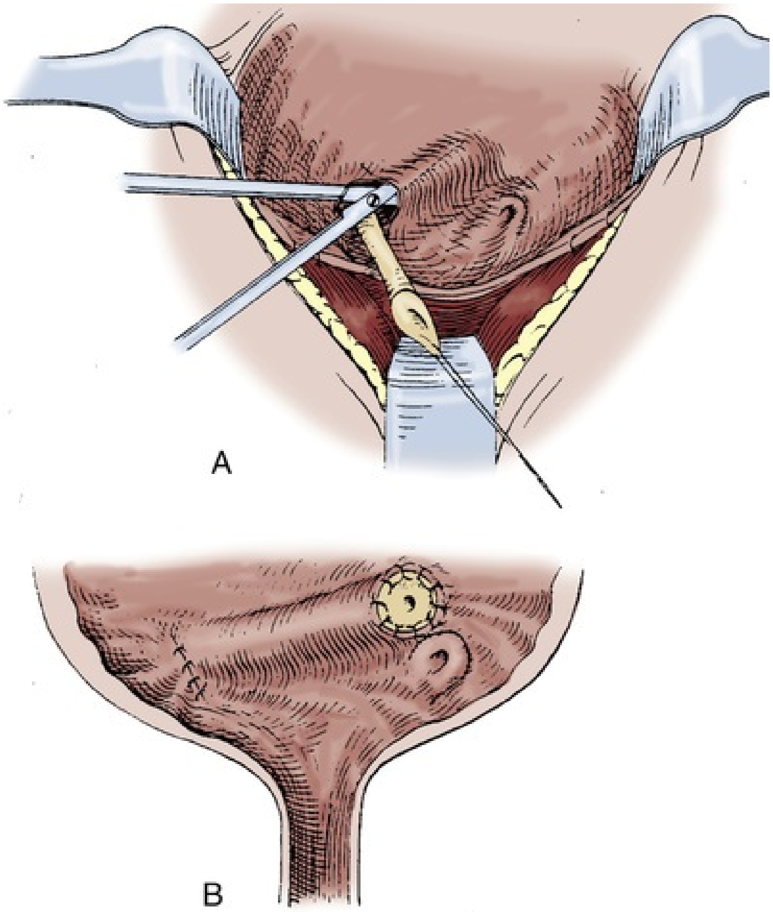
Cohen Cross-Trigonal Technique

Cohen's procedure allows for a longer tunnel length by directing it toward the opposite ureteric orifice across the trigone/transhiatally. The technique was originally described in 1977 and has become the most common intravesical procedure because of its versatility, simplicity, and reliable results, with success rates upward of 98% (Cohen, 1977; McCool and Joseph, 1995; El-Ghoneimi et al., 1999; Androulakakis et al., 2003). The technique is especially suited for thick-walled trabeculated bladders as the trigone is typically spared from distortion, and when concomitant bladder neck reconstruction is planned as the transverse tunneling of ureters allows for an increased length, for bladder neck reconstruction. One major critique of the procedure relates to future difficult endourologic retrograde catheterization of the ureters for radiographic studies, stent placement, and management of urolithiasis. This shortcoming can be overcome by negotiating the reimplanted ureteric orifice with a modern flexible ureteroscope or combining cystoscopy with suprapubic cystostomy by trocar or an intravenous cannula directed toward the ureteric orifice, through which a guidewire is introduced under cystoscopic vision (Wallis et al., 2003; De Castro et al., 2011; Emiliani et al., 2017).

After intravesical mobilization of the ureter, a submucosal tunnel is developed using tenotomy scissors in the direction of the opposite ureteric orifice. When only one ureter is reimplanted, the tunnel is directed superior to the contralateral orifice. If bilateral reimplantation is contemplated, the tunnel for the more laterally displaced ureter is directed superior to the contralateral orifice. The second ureter is directed toward the inferior edge of the orifice of the laterally displaced ureter. Reimplantation in a common tunnel has also been described with excellent outcomes (Androulakakis et al., 2003). After pulling the ureter through the new tunnel, it is hitched in place as mentioned earlier (Fig. 42.20).



A
B

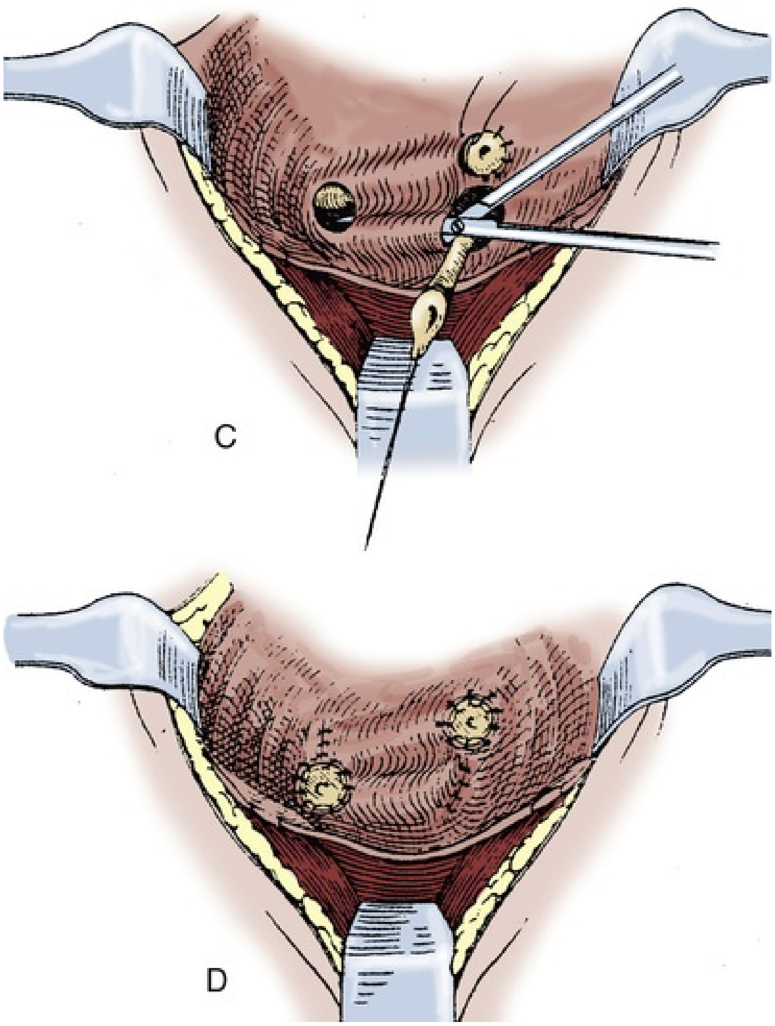


FIG. 42.20 Cohen cross-trigonal unilateral reimplantation technique. After the ureter is freed (A), a submucosal tunnel is made, with the new mucosal hiatus just above the contralateral ureteral orifice (B). Bilateral reimplant. (C) The more superior ureter is tunneled transversely, with its new orifice just above the contralateral orifice. (D) The other ureter is tunneled inferiorly, with its new orifice located at the inferior-most portion of the contralateral hiatus.

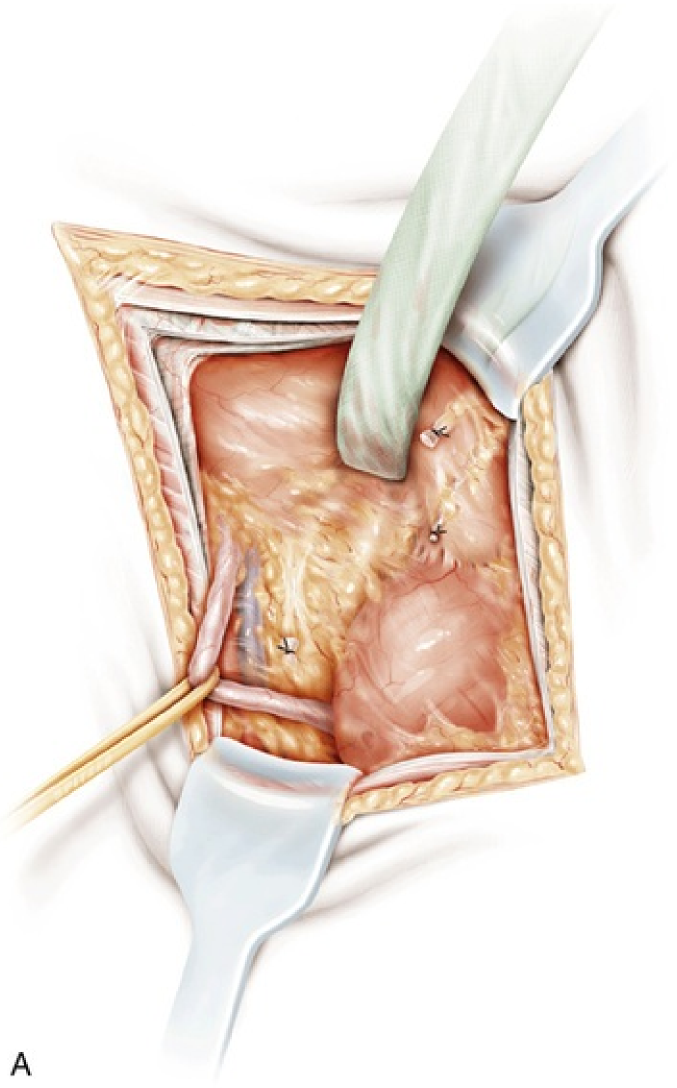
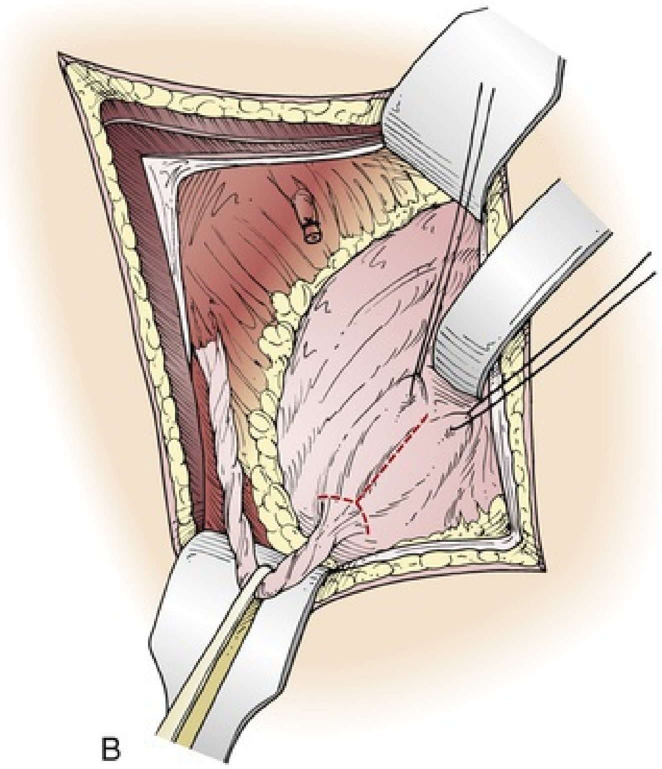
Extravesical Procedures

In the 1960s, Lich and Gregoir independently described an extravesical approach for ureteric reimplantation, which has since eponymously borne their names and become a widespread and popular procedure (Lich et al., 1961; Gregoir, 1964). Several consequent modifications have been introduced helping to popularize the method (Daines and Hodgson, 1971; Zaontz et al., 1987), although ensuing neuroanatomic studies by Leissner et al. and Yucel and Baskin have swung the pendulum back to the original description (Leissner et al., 2001; Yucel and Baskin, 2003). **In this extravesical procedure, the bladder is not opened, thus avoiding problems of postoperative hematuria and bladder spasms**. The detrusor along the course of the ureter is incised down to the urothelium, which is left intact, and the ureter is placed and secured in the detrusorotomy, thereby creating an antireflux tunnel. Concerns with this procedure relate to development of postoperative, usually transient, bladder dysfunction and voiding difficulty in up to 20% necessitating catheterization, especially after bilateral procedures (Fung et al., 1995; Lipski et al., 1998; Barrieras et al., 1999; Marotte and Smith, 2001). This has been related to injury of the neural innervation of the detrusor and trigone occurring during dissection of the ureter and subsequent detrusorotomy. To overcome this, elegant studies by Leissner and Yucel delineating the neuroanatomic topography of the UVJ have enabled better understanding of the surgical anatomy of this very intricate region and allowed for modifications that have lessened the incidence of postoperative voiding dysfunction (David et al., 2004; Palmer, 2009). **In Leissner's cadaveric study, it was shown that the main portion of the pelvic plexus is located approximately 1.5 to 2 cm dorsal and medial to the UVJ in adult specimens**. Smaller nerve branches travel along the medial aspect of the ureter outside the thin layer of tissue (mesoureter), which surrounds the ureter. Therefore according to the findings of this study, neural injury can be minimized by staying close to the ureter when dissecting and by avoiding the area dorsomedial to the UVJ (Leissner et al., 2001). These findings were further supported by fetal autopsy studies conducted by Yucel and Baskin using immunohistochemical staining and three-dimensional imaging, **which confirmed the localization of the nerves on the medial border of the ureter just outside the Waldeyer sheath and showed them to extend circumferentially around the ureter and beyond its entry point in the bladder distal and lateral to the UVJ along the detrusor** (Yucel and Baskin, 2003).

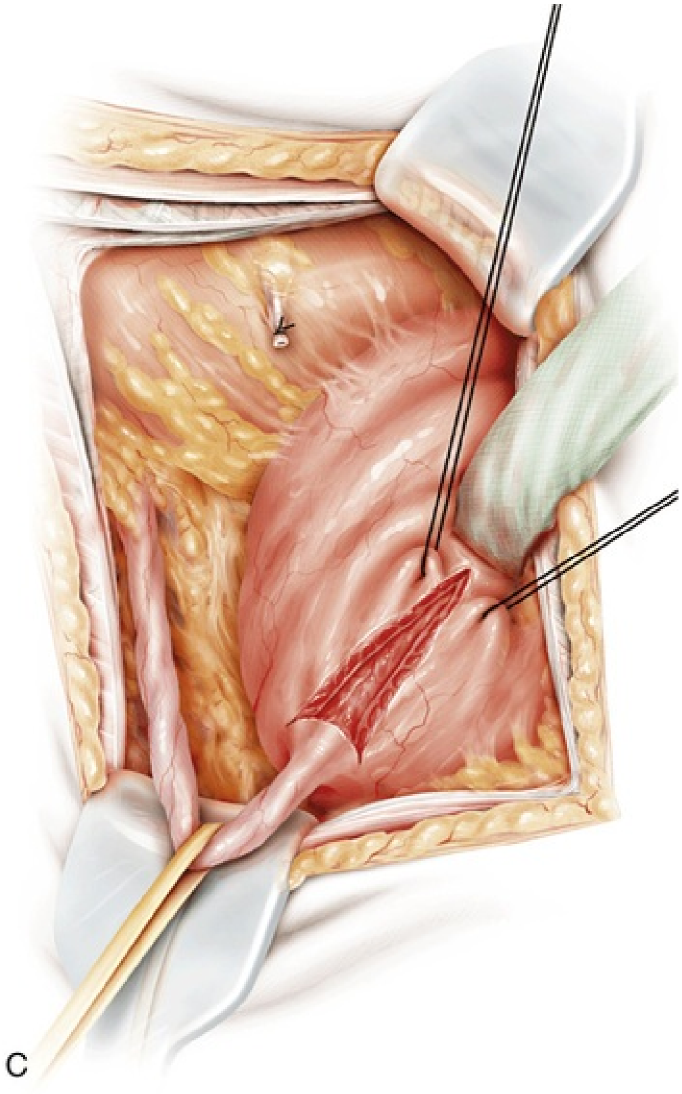
The procedure itself can be performed through a standard Pfannenstiel incision or through and inguinal incision for the unilateral cases (Howe and Palmer, 2017). The bladder, which should be filled to about one-third of its volume, is cleared of its peritoneal attachments. The obliterated umbilical artery is identified and divided, thereby facilitating the dissection and mobilization of the distal ureter. The peritoneum is teased off the anterior surface of the ureter, with the dissection staying close to the ureter to avoid injuring the nerves but also minding the ureter's blood supply. A vessel loop can then be passed behind the ureter and used as a handle for gentle traction. The ureter can then be mobilized to the level of the UVJ, where dissection should stop to avoid injuring the small nerves that circumscribe the ureter and branch out to the detrusor lateral and distal to the UVJ. Once the ureter is mobilized, and with the moderately distended bladder in its normal anatomic position, the planned 5-cm tunnel is identified along the natural course of the ureter and marked with a surgical pen. The bladder can then be retracted medially to facilitate dissection. The detrusor is incised with monopolar diathermy at low wattage. As the incision is carried deeper, the assistant can pick up individual detrusor fibers with forceps to be divided by the surgeon. This will result in the formation of a uniform mucosal bulge through the detrusorotomy. The detrusor can then be separated from the mucosa on both sides by gentle blunt dissection with a pledget, to create detrusor flaps that can accommodate the ureter without causing constriction. In Zaontz's modification of the original Lich-Gregoir procedure, the detrusorotomy is continued around the UVJ to allow for placement of advancement sutures from the ureter into the trigone (Zaontz et al., 1987). This step may have been responsible for some of the voiding dysfunction reported in the era where this modification was popularized as this dissection encroaches on vital neural innervation of the detrusor and is generally now avoided as is the case when the procedure is done laparoscopically. It can be helpful to place a stay suture at the cranial apex of the incision to maintain traction and to control tunnel length. Once complete, the tunnel can then accommodate the ureter, and the detrusor can be reapproximated using interrupted 4-0 monofilament absorbable sutures in a caudocranial direction, remembering to incorporate the ureteral adventitia in several of these sutures, especially at the apex, so as to stabilize tunnel length and to prevent prolapse or slippage of the ureter (Fig. 42.21). Postoperatively, the bladder is drained by a Foley catheter for 24 to 48 hours, and the child can be discharged as soon as spontaneous voiding has commenced.



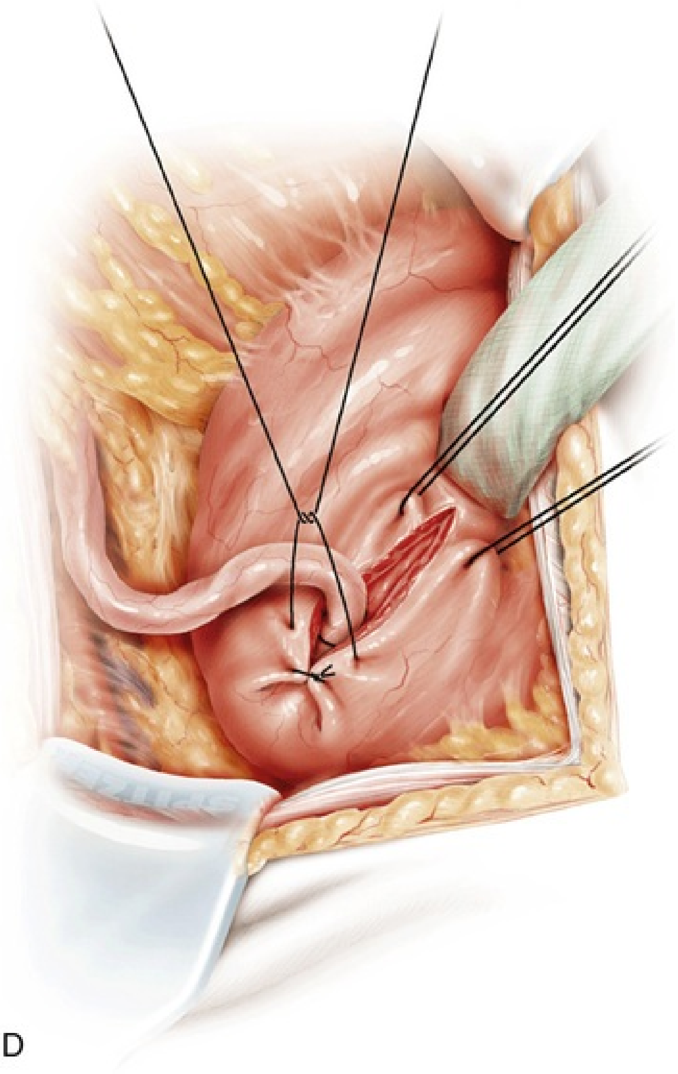
A



B



C



D

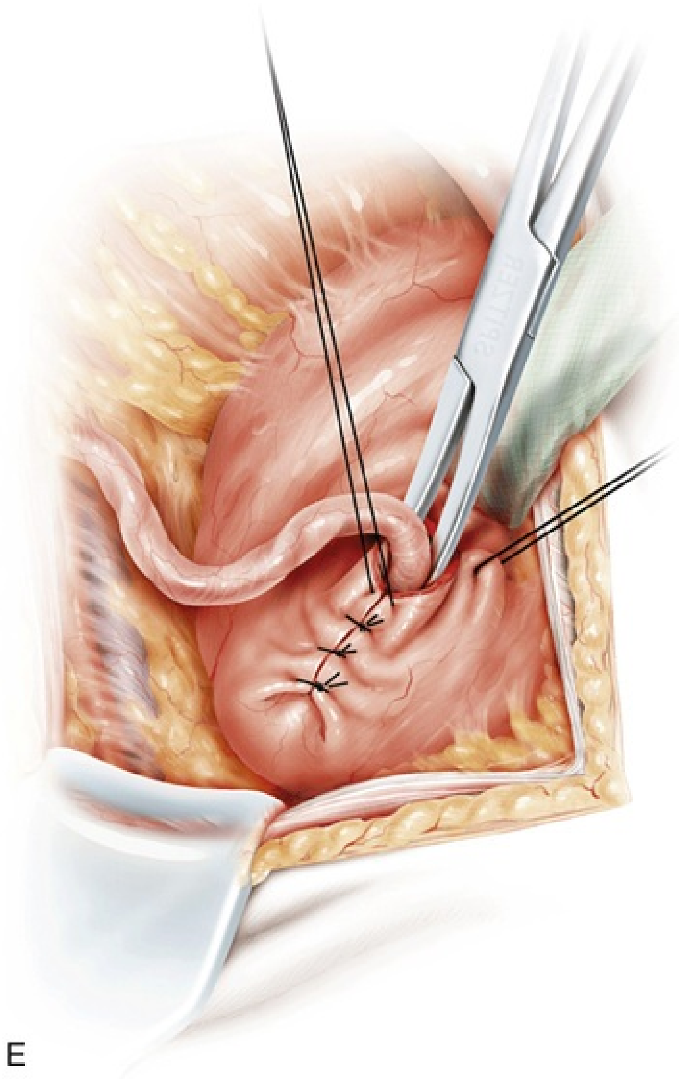


FIG. 42.21 Lich-Gregoir technique. After the obliterated umbilical vessels are divided and tied off, the ureter is identified and the peritoneum is teased off its anterior surface. A vessel loop can then be passed behind the ureter and used as a handle for gentle traction (A). Along the course of the ureter, the planned tunnel of 5 cm can be marked on the detrusor (B). The bladder can then be retracted medially to facilitate dissection of the detrusor along the marked line down to the urothelium, allowing detrusor flaps to be raised (C). The ureter is now placed in the detrusorotomy, and the flaps are closed over it incorporating ureteral adventitia in several of the stiches (C to E). A stay suture at the apex of the detrusorotomy maintains orientation and detrusor tunnel length.

Minimally Invasive Procedures

Since the initial reports by Ehrlich and Janetschek in the mid-1990s, which showed the feasibility of applying the then-emerging concept and technology of laparoscopic surgery for successful extravesical reimplantation of refluxing ureters, an almost exponential interest and rise in minimally invasive procedures has been evident (Ehrlich et al., 1994; Janetschek et al., 1995). However, because of its long learning curve and the cumbersomeness of especially intracorporeal suturing, laparoscopic antireflux surgery never saw widespread adoption, with percentages never exceeding 20% of all minimally invasive procedures performed in the United States, which generally only represented a mere 6.3% of all ureteral reimplants in 2012 (Bowen et al., 2016). **Initial reports seemed however to indicate benefits associated with minimally invasive procedures such as decreased pain, hematuria, and bladder spasms in addition to shorter length of hospital stay** (Lakshmanan and Fung, 2000; Gill et al., 2001; Yeung et al., 2005; Canon et al., 2007b). This spurred on the adoption of robotic-assisted laparoscopic techniques with the advent of the da Vinci Surgical System (Intuitive Surgical, Mountain View, CA). After a porcine study by Olsen et al. showed the feasibility of robotic-assisted intravesical cross-trigonal ureteral reimplantation, Peters and Woo used the robotic system for performing bilateral intravesical Cohen ureteral reimplantation in six children (Olsen et al., 2003; Peters and Woo, 2005). This was soon followed by reports of successful robotic-assisted laparoscopic extravesical reimplantations (Casale et al., 2008; Marchini et al., 2011; Smith et al., 2011; Bayne et al., 2012; Kasturi et al., 2012; Schomburg et al., 2014).

Even though both laparoscopic and robotic-assisted ureteral antireflux surgery apply the same surgical principles as those of open surgery, albeit using minimal access, early reports failed to reproduce the high success rates reported by classical open surgeons of 95.9% shown in a review of 86 studies reporting on 6472 patients (8563 ureters) (Elder et al., 1997). Reflux resolution rates of 83% to 92% were not uncommon, and outcomes were marred by “high” complication rates that were unusual after open procedures such as ureteral injury, obstruction, and urinary leakage especially after the intravesical vesicoscopic procedures (Peters and Woo, 2005; Kutikov et al., 2006b; Canon et al., 2007a; Kurtz et al., 2016). More recent multi-institutional reviews have also documented success rates that continue to fall short of the gold standard approach of open reconstruction and higher complication rates (Grimsby et al., 2015; Boysen et al., 2017). It can however be argued that laparoscopic and robotic-assisted laparoscopic procedures have been subject to more rigorous postoperative radiographic follow-up for documentation of reflux resolution than what historically has been the case for open procedures and that the trend with increasing experience has been that of success and complication rates slowly but surely approaching those of open reconstruction. With laparoscopic ureteral reimplantation procedures confined to few centers, robotic-assisted ureteral reimplants appear to have overtaken the field, and their adoption, though still limited, seems to be increasing steadily in number as has been evident within the past two decades (Bowen et al., 2016). Due to inherent problems with creating and maintaining pneumovesicum, in addition to the very confined working space for the articulating instruments of the robot inside the bladder, extravesical methods are gaining momentum with ever-increasing cohort size reports and improving results (Smith et al., 2011; Akhavan et al., 2014; Schomburg et al., 2014; Gundeti et al., 2016; Boysen et al., 2018).

Robotic-Assisted Laparoscopic Ureteral Reimplantation–Extravesical (RALUR-EV)

The patient is placed in the low lithotomy position, all pressure points are padded, and the skin is prepped and draped from the xiphoid to the perineum. A bladder catheter is inserted in the sterile field, for urine drainage and filling of the bladder. A 12-mm camera port trocar is placed intraperitoneally through the lower umbilical fold by Hasson's open technique. Under direct vision, two 8-mm robotic trocar ports are placed in the midclavicular line just below the level of the umbilicus. Use of an extra 5-mm assistance port is adantageous for delivering sutures and suction. The robot is docked between the legs, with bipolar diathermy used on the left and monopolar scissors on the right when the surgeon is right handed. The ureter is identified at the pelvic brim and mobilized down to the UVJ taking care not to injure the vas deferens, which is easily identified. Dissection is kept close to the ureter to avoid the neurovascular bundle dorsomedially. A stay stitch in the bladder for traction may be placed to enhance visualization. Saline is instilled to partially fill the bladder to facilitate detrusorotomy. A 4- to 5-cm *Y*-shaped detrusorotomy in line with the course of the ureter is created, and detrusor flaps are raised to allow enough space for accommodation of the ureter without constriction. The ureter is placed within the tunnel, and the flaps are closed using a running 4-0 absorbable monofilament suture in a caudocranial direction. Again, as in the classical open Lich-Gregoir procedure, the ureteral adventitia is incorporated in several of these sutures, especially at the apex, to stabilize tunnel length and to prevent prolapse or slippage of the ureter (Fig. 42.22).

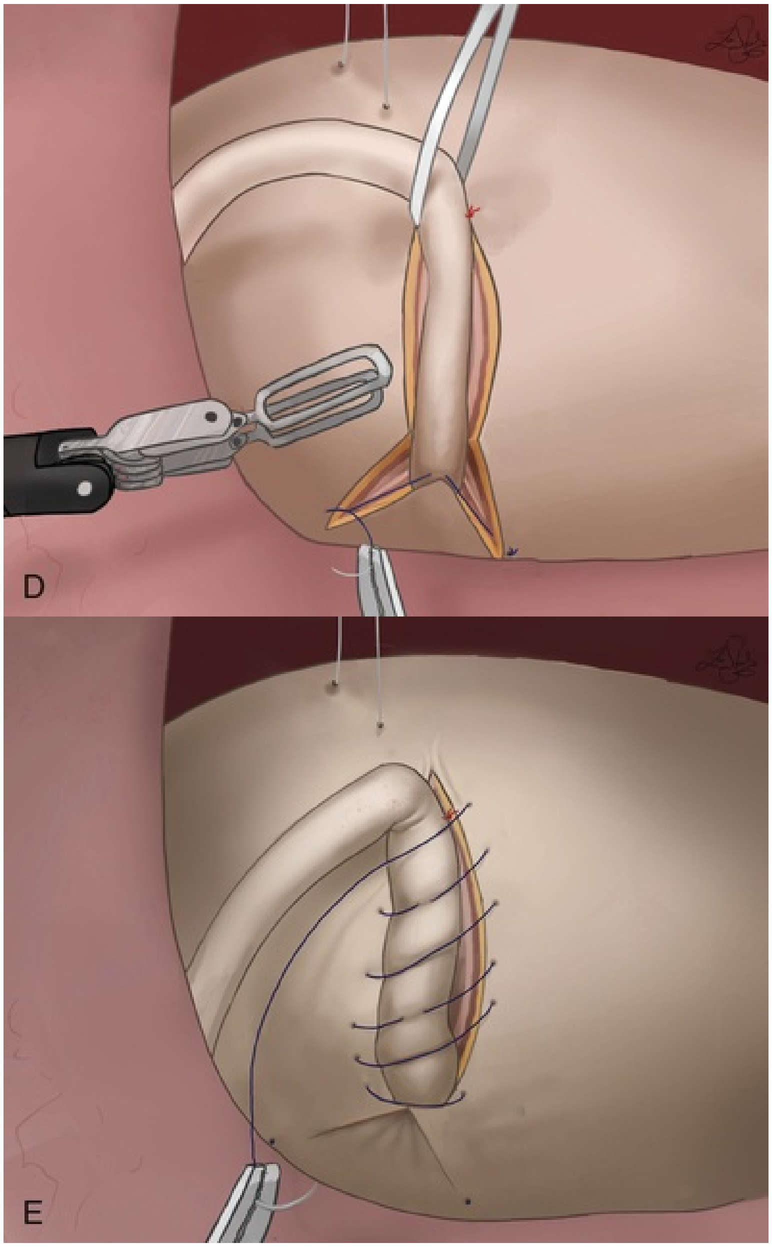

FIG. 42.22 Robotic Assisted Laparoscopic Ureteral Reimplantation–Extravesical (RALUR-EV) technique. The patient is positioned, prepped, and draped in the low lithotomy position, with port placement as in (A). The ureter is identified at the pelvic brim, and an umbilical tape is passed to allow atraumatic handling taking care not to injure the uterine artery (B) or the vas deferens (C). As in the open technique, a *Y*-shaped detrusorotomy along the natural course of the ureter is created about 5 cm long. (D, E) The ureter is then embedded into the tunnel, which is closed with a running 4-0 resorbable suture in a caudocranial direction, again incorporating ureteral adventitia into the running stich. A stay suture at the apex of the detrusorotomy maintains orientation and detrusor tunnel length. (A, from Gundeti MS, Boysen WR, Shah A. Robot-assisted laparoscopic extravesical ureteral reimplantation: technique modifications contribute to optimized outcomes. *Eur Urol* 2016;70(5):818-823.)

Postoperative Evaluation

In expert hands, the success rate for ureteroneocystostomy in patients with low-grade primary VUR approaches 100%. As a result of these outstanding outcomes, several centers have evaluated the need for postoperative invasive imaging. Most agree that a sonogram is necessary at 6 to 12 weeks postoperatively, as also indicated in the most recent AUA Guidelines on Vesicoureteral Reflux (Peters et al., 2010). In a large study by Barrieras et al., 723 renal units were evaluated (Barrieras et al., 2000). At 1 year postoperatively, there was a significant difference between children who had undergone surgery for low-grade primary VUR (99% resolution) versus those with high-grade reflux (94%). Thus, in patients who initially had low-grade primary reflux and in whom the preoperative and postoperative ultrasound examinations were normal and do not have voiding dysfunction or recurrent UTIs (Lavine et al., 2001), the success rate with uncomplicated ureteroneocystostomy approaches 100% (El-Ghoneimi et al., 1999; Barrieras et al., 2000; Grossklaus et al., 2001; Canning, 2002). On the basis of these reports, it has been suggested that the postoperative voiding cystourethrogram (VCUG) can be avoided in this group of patients. It may, however, be reasonable to perform postoperative studies in children with a dysfunctional bladder or in those who develop postoperative hydronephrosis or UTIs. The lower success rate for high-grade reflux would still support complete postoperative studies in most cases.

Complications of Ureteral Reimplantation

Early Complications

Persistent Reflux.

Early reflux after ureteroneocystostomy usually is not a significant clinical problem and commonly resolves by 1 year on repeat cystography. In the report by Barrieras et al., 49 of 723 renal units had reflux at 3 months, 11 of which were contralateral (Barrieras et al., 2000). At 12 months follow-up, reflux resolved spontaneously in 20 of the 38 ipsilateral ureters and in 8 of the 11 contralateral ureters. Persistent reflux at 1 year was more common in patients who had high-grade reflux preoperatively. In their study, 30% of patients undergoing surgery had high-grade reflux. Two-thirds of those with persistent reflux at 1 year (12 of 18) were from that group. **Thus the majority of low-grade postoperative reflux detected by the initial VCUG at the 3-month follow-up point disappeared spontaneously**, likely because of the resolution of the bladder inflammation and improvement in bladder dysfunction that may be present in the early postoperative period.

Contralateral Reflux.

A small percentage of patients undergoing unilateral ureteral reimplantation have been known to develop postoperative contralateral reflux. Given that bilateral reimplantation is highly successful, it can be argued that all patients with VUR should undergo a bilateral procedure regardless of the laterality or bilaterality of the condition. Studies specifically looking at this subgroup of patients have documented a high-resolution rate of contralateral VUR, thereby contradicting the need for such an aggressive stance. **In a study by Hubert et al. detailing the results of 395 patients, contralateral VUR was documented in 9.9%, of which 77.8% resolved spontaneously at a median of 21.5 months** (Hubert et al., 2014). Similarly, Minevich et al. and Burno et al. found low rates of contralateral VUR in 5.6% and 11.6% in their respective cohorts with spontaneous resolution occurring in the overwhelming majority with observation alone (Minevich, et al. 1998; Burno et al., 1998). Contralateral VUR was found more likely in young patients (<6 years of age) and in those with low bladder capacity (<50% of expected) or reimplantation of a refluxing duplex system. There was also a tendency toward higher grades of corrected reflux being associated with contralateral VUR (Diamond et al., 1996; Hubert et al., 2014), however, no association was found with regard to the surgical procedure employed. The exact mechanisms underlying new-onset contralateral VUR remains speculative. It has been attributed to a distortion of the contralateral hemitrigone, the result of a pop-off mechanism, or that contralateral VUR in fact is synchronous (i.e., bilateral) but missed on the initial cystogram or that the natural history of unilateral or bilateral reflux may involve intermittent appearance and disappearance of VUR on one side (Sparr et al., 1998). Recommendations for management of contralateral VUR range from observation in the majority of cases to intervention for control of clinical pyelonephritis episodes. In asymptomatic children younger than 4 to 5 years of age, prophylactic antibiotics are warranted for postoperative contralateral reflux, particularly if one is to be consistent with the medical therapy for the previous ipsilateral reflux. If the child remains asymptomatic and infection free, repeat VCUGs may not be necessary because contralateral reflux resolves spontaneously in the majority of children.

Obstruction.

It is not unusual to detect a mild to moderate degree of hydronephrosis in the early postoperative period by ultrasonography. This should resolve spontaneously with time. Acute postoperative obstruction may be related to technical issues such as twisting or kinking of the ureter in its new tunnel, intramural blood clots, or extramural compression by submucosal hematoma or edema at the site of anastomosis. Progressive, significant obstruction usually becomes apparent in the first 2 weeks after surgery. The children typically present with symptoms of acute ureteral obstruction, including acute abdominal pain, nausea, and vomiting. Although infection is less common, if it occurs it is quite significant in the obstructed system. The diagnosis is readily made on ultrasonography, and the severe hydroureteronephrosis is confirmed by delayed function and excretion on renal scintigraphy. In the more significant cases, drainage of the system either by retrograde insertion of a double pigtail catheter or a percutaneous nephrostomy tube may be necessary. The nephrostomy tube should be internalized as early as possible to avoid a dry reimplant. Many of these cases resolve without requiring additional surgery.

Long-Term Complications

Obstruction.

Progressive dilation and obstruction of the reimplanted ureter can result from ischemia of the distal ureter, which can occur if dissection has been aggressive and carried too close to the ureter's delicate blood supply. Angulation of the ureter at its entry into the bladder can likewise cause obstruction especially if the neo-hiatus is positioned too laterally or anteriorly on the bladder wall. This will result in kinks that worsen as the bladder fills. This situation might resolve spontaneously; alternatively, it might need stenting or redo surgery. Other causes of obstruction include an underdeveloped submucosal tunnel, which may lead to constriction of the ureter within the tunnel, and stenosis of the neo-ureteral orifice. Management options include balloon dilation and stenting, or unroofing the distal few millimeters of the tunneled ureter to relieve the obstruction while maintaining the antireflux mechanism. If these interventions fail reimplantation is indicated.

Recurrent or Persistent Reflux.

Failure of antireflux procedures in primary low-grade reflux is extremely rare. Most failures are caused by either high-grade reflux or an inadequate ratio of tunnel length to ureteral diameter. Development of a short tunnel and failure to taper the excessively wide ureter are obvious important factors. Another significant cause of persistent or recurrent reflux is failure to recognize secondary reflux, especially associated with neurogenic bladders and posterior urethral valve bladders. **Reflux in these situations is secondary to the poor storage or emptying characteristics of the bladder. These issues need to be addressed and optimized before reimplant surgery is attempted** (Peters et al., 2010). In most situations, improving bladder storage and/or emptying with a combination of an anticholinergic agent and intermittent self-catheterization results in spontaneous resolution of secondary reflux (Agarwal et al., 1997). Proceeding with reimplantation surgery in the presence of an abnormal bladder results only in worsening of the ureteral dilation and deposition of scar tissue in the pelvis, which would render future attempts at correcting the reflux even more difficult.

Reoperative Reimplantation

Redo reimplantation is technically more challenging and requires careful attention to detail and meticulous surgical technique. Dissection of the ureter and extensive mobilization are required to achieve an adequate submucosal tunnel. Careful dissection of the ureter is best accomplished by a combination of extravesical and intravesical mobilization as needed. The ureter should be carefully evaluated and ischemic segments excised. Free bleeding from the divided distal end should be observed in addition to peristaltic activity, ensuring normal musculature and blood supply. It is preferable to create a new hiatus and submucosal tunnel. If the ureter is short, a psoas hitch can be used to facilitate the creation of the antireflux mechanism. The psoas hitch should be carried out with a nonabsorbable suture before creation of the submucosal tunnel. The bladder is fixed to the psoas muscle sheath on either side of the iliac vessels, providing a stable posterior bladder wall. In children, the bladder can be mobilized sufficiently to bring it up almost to the bifurcation of the common iliac vessels. This may provide adequate bridging for a distal ureteral defect. A psoas hitch can be achieved only on one side. Attempting a psoas hitch on both sides will not provide adequate length on either side and thus should be avoided. If both ureters are shortened, consider a psoas hitch on one side to achieve a satisfactory antireflux mechanism with a transureteroureterostomy for the other ureter.

Other techniques to consider for the short ureter include the Boari flap, in which a flap extending from the dome to the anterior wall of the bladder based on the posterior wall can be rotated proximally. The flap should be wide enough to allow creation of a submucosal tunnel and tubularization of this flap. In the short ureter, a nipple valve can be created in association with a short submucosal tunnel (Routh et al., 2009). The nipple valve is particularly useful in dilated ureters and is fashioned by spatulating the ureter and folding it back onto itself (Paquin, 1959).

In situations in which the ureter is significantly foreshortened, it can be replaced using a reconfigured segment of bowel as described by Pope and Koch (Pope and Koch, 1996). The colon or ileum is reconfigured similar to the Monti procedure. This technique offers important advantages over the classic tapered ileal ureter, allowing a long tube to be created from a short segment of colon without tapering, thus eliminating the metabolic consequences; additionally, the mesentery is in the center of the tube, which facilitates creation of the submucosal tunnel.

Endoscopic Treatment of Vesicoureteral Reflux

In 1981, the German urologist Matouscheck introduced the concept of endoscopic injection in the treatment of VUR (Matouschek, 1981). Using Teflon, his technique was popularized by O'Donnell and Puri, who coined the acronym STING (Subureteric Teflon Injection) to describe their procedure (O'Donnell and Puri, 1986). Teflon injection was used in many countries but never achieved FDA approval in the United States because of concerns regarding migration of PTFE particles. However, the simplicity of the endoscopic procedure together with high success rates in resolving VUR invigorated the search for and development of safer materials. Currently, Dextranomer/hyaluronic acid (Dx/HA) (Deflux™) is the most commonly used material, with initial resolution rates of 90% for the treatment of low-grade primary VUR after a single treatment (Kirsch et al., 2004). Subsequent results have been less consistent, probably because of variations in technique and the definition of successful outcome.

Technique of Endoscopic Injection

Läckgren and Kirsch have meticulously described both the traditional STING technique and the hydrodistension implantation technique (HIT) including the double HIT (Brandstrom et al., 2010). O'Donnell and Puri originally described the classic STING technique (O'Donnell and Puri, 1984). Prophylactic antibiotics are usually administered with induction of anesthesia. A cystoscopy should be carried out before unpacking the injectable materials in case the procedure cannot be performed because of inflammatory changes in the bladder. If a rigid needle is used, an offset lens injection scope is the appropriate choice. A flexible needle can however easily be inserted through a standard 0- or 30-degree lens cystoscope. The size of the needle varies depending on the viscosity of the material and ranges from 3.7 to 5 Fr. The viscosity of the material also determines whether injecting the material can be carried out using a regular syringe or if it requires a ratcheted metal syringe holder. A 3-Fr ureteral catheter may be introduced to lift up the anterior wall of the ureter and identify the axis of the tunnel. The needle is inserted with the bevel facing up at the 6 o'clock position. The original description by O'Donnell and Puri suggested entering the mucosa 2 to 3 mm distal to the UVJ and advancing the needle in the submucosal plane for a distance of 4 to 5 mm. Kirsch et al. popularized this approach (submucosal implantation within the intramural ureter) and reported improved results with all grades of reflux compared with the classic technique (92% vs. 79% of ureters) (Kirsch et al., 2004). They further modified the technique with addition of a second injection inside the orifice and named it the double hydrodistention implantation technique (double HIT), resulting in further improvement (93%) in intermediate and long-term results (Kalisvaart et al., 2012).

The accuracy of the needle entry point and needle placement is paramount for successful outcome of the procedure (Fig. 42.23). An improper puncture may not result in the desired mound formation and thus may not provide adequate support for the UVJ. If the needle requires repositioning, the implanted material may leak out of the first puncture site, resulting in failure of the procedure.

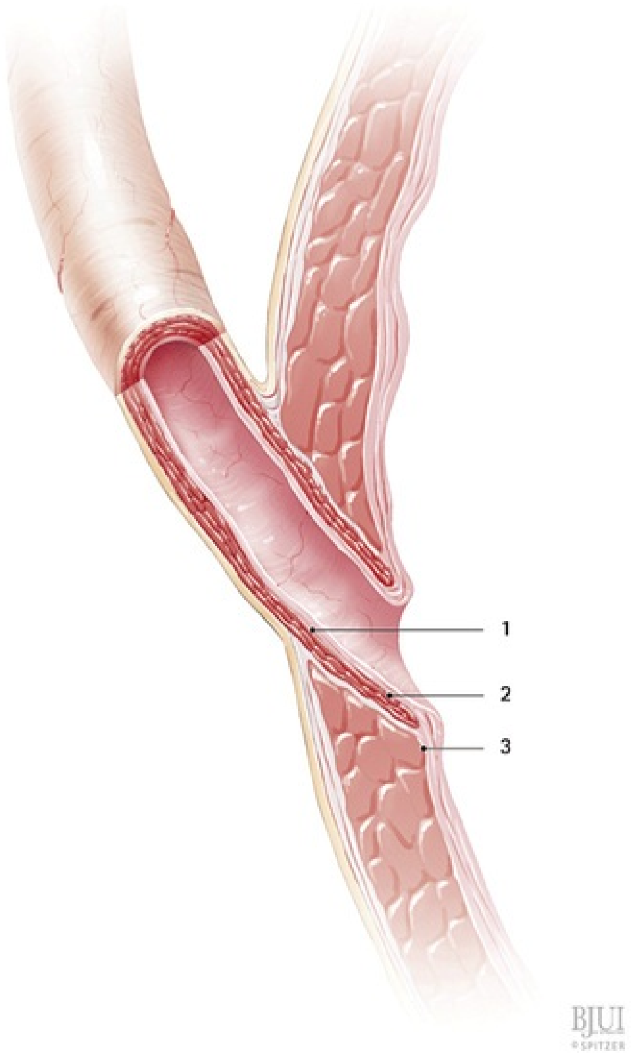

FIG. 42.23 Injection sites for endoscopic treatment of vesicoureteral reflux. *1* and *2*, Hydrodistension (double HIT) technique with submucosal injection of the material in the transmural ureter. *3*, The classic STING technique with the material injected under the bladder mucosa just below the ureteral orifice.

Injection should be carried out slowly. If the needle is positioned in the submucosal plane, the mound becomes apparent with the initial injection of 0.1 to 0.2 mL. This is a key point in the procedure; unsatisfactory mound formation and location after this initial injection is an indicator that the tip of the needle is not in the proper position. Repositioning of the needle by withdrawing it slowly and then advancing it while injecting, in addition to rotating the bevel gently (depending on the lateral location of the mound), should help achieve the desired effect. **Once a volcano appearance, with the ureteral meatus on top of the mound, is achieved, additional volume is injected until the ureteric orifice**

becomes crescent or slit shaped (Fig. 42.24). The shape of the mound was found to be a significant predictor of a successful outcome. Achieving a volcano-shaped mound was associated with an 87% success rate, whereas other morphologies were associated with only a 53% success rate (Lavelle et al., 2005). For most materials, the needle should be kept in place for 1 minute at the end of the injection to reduce extrusion of the material at the injection site. With Deflux, this step is not essential. The bladder is emptied, and the mound is inspected with an empty and a full bladder to ensure that adequate support of the ureter is persistent. Rarely, bleeding occurs at the puncture site. This is best dealt with by emptying the bladder and applying gentle pressure with the tip of the cystoscope until the bleeding stops. Cauterizing the area is not advisable as it may result in sloughing of the mucosa and extrusion of the injected material. At the end of the procedure, lidocaine gel may be instilled in the urethra; catheter drainage is not necessary. In general, the child spends a brief amount of time in the recovery room, followed by discharge. All activities can be resumed immediately.

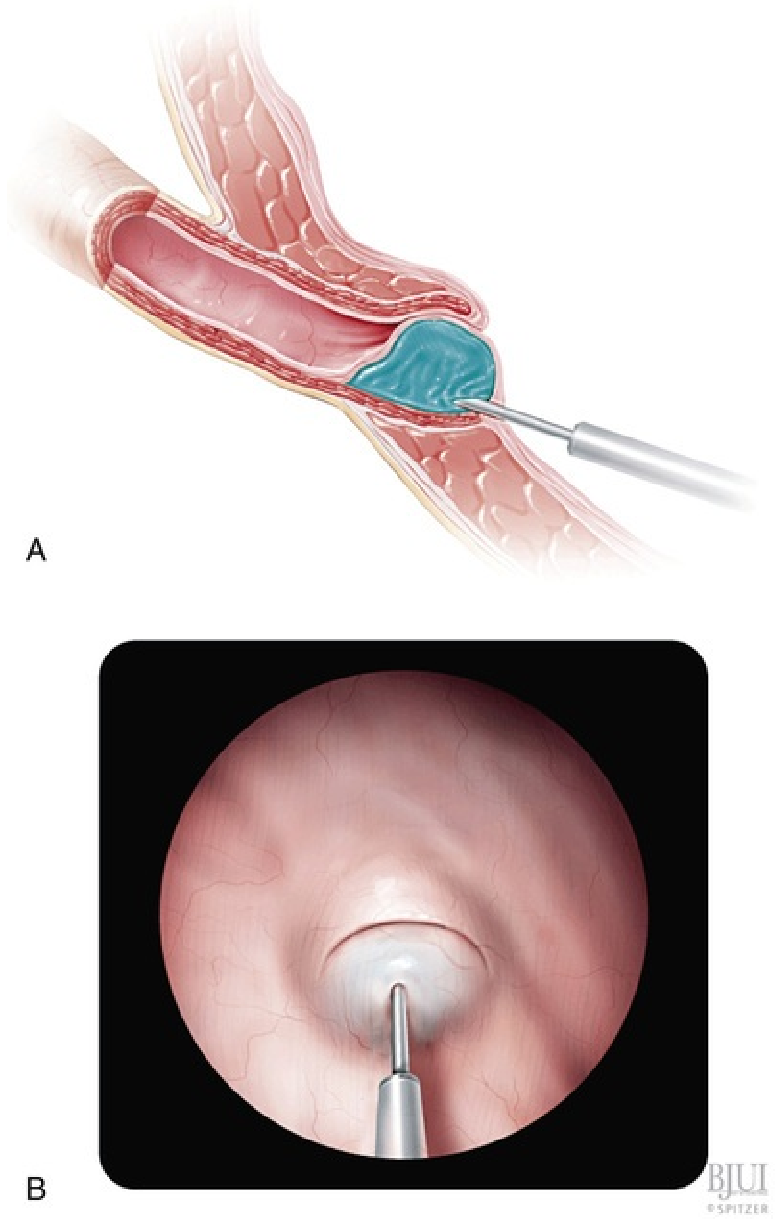

FIG. 42.24 Intraureteral injection (HIT) technique. The material is injected under the intramural ureteral mucosa (A). Appearance of the mound after completion of the injection with a slit-like orifice (B).

There is a significant learning curve with endoscopic correction of VUR (Herz et al., 2001). Although the technique is quite simple once learned, there are some technical nuances and details that require specific attention.

Follow-Up

The child is maintained on antibiotics for 3 months. An early ultrasonography 2 to 4 weeks after treatment is advisable to exclude acute obstruction caused by the bulking substance. A follow-up sonogram and VCUG are obtained after 3 months. However, this depends on the clinical situation. When the clinical situation is improved, simple follow-up by ultrasonography should be sufficient. If VUR persists, one to two repeat injections can be considered. If there is still no resolution, open, laparoscopic, or robotic surgery is recommended. A significant number of late-onset ureteric obstructions have recently been reported, which may argue for long-term follow-up with ultrasonography (Karakus et al., 2016; Kocaoglu, 2016; Ben-Meir et al., 2017; Warchol et al., 2017).

Most reports to date have not indicated any significant difficulty with open surgery after endoscopic correction using Deflux (Herz et al., 2001; Lackgren et al., 2001; Friedlander et al., 2018), but some have experienced difficulty with other substances (Crozier et al., 2016). At open surgery, the injected material is either not seen at all or is found well encapsulated but in an incorrect plane or location inside or outside the bladder. The material is easily removed en bloc and the reimplant procedure carried out without difficulty in most cases.

Materials Used for Endoscopic Correction of Reflux

For an injectable biomaterial to be ideal, it must be nontoxic and stable without migration to vital organs. It should cause minimal local inflammation, while being well encapsulated by normal fibrous tissue and fibrocytes. The material should be easy to inject through a long needle that passes easily through most standard endoscopic instruments. It must be viscous enough to prevent leakage from the puncture site and maintain its injected volume and the mound shape after the normal process of exchange and excretion of any carrier molecules.

The concern with the particulate agents is migration and with degradable agents is durability. Distant migration can occur by two mechanisms. The first is expansion of the injected bolus, which may lead to disruption of the small vessels in the area of the distal ureter and trigone, resulting in the material gaining intravascular access. Particles smaller than 50 μm may bypass the pulmonary vascular bed and thus access the systemic circulation and reach other organs in the body. The second migration mechanism is by phagocytosis of the injected particles by tissue macrophages or blood-borne monocytes. The particle size determines whether phagocytosis can occur, because it is generally agreed that phagocytosis requires a particle less than 80 µm in diameter.

Most of the agents used for endoscopic treatment of VUR are **nonautologous materials.**

Polytetrafluoroethylene paste (Teflon paste) has been widely used for many years in various surgical procedures and as a component in grafts and sutures and as a bulking agent for urinary incontinence. This inexpensive material was advocated for the endoscopic treatment of VUR, with success rates of 86% after one to four injections (Puri et al., 1995; Chertin and Puri, 2002) and a durability of 95% after 11 to 17 years on long-term follow-up (Chertin and Puri, 2002). The material has all but been abandoned because of concerns with migration of the small Teflon paste particles (90% of the particles are less than 40 µm in diameter).

Polydimethylsiloxane (PDS) (Macroplastique) is a solid silicone elastomer that has been used as a soft tissue bulking agent. The injectable material is composed of soft, flexible, highly textured implants of heat-vulcanized PDS suspended in a bioextractable carrier gel. The carrier gel is a water-soluble low–molecular-weight polyvinylpyrrolidone hydrogel (Povidone). The carrier gel is absorbed and replaced with host fibroblasts that subsequently deposit collagen, encapsulating the implant. The implant retains its size and shape. To minimize the risk for migration, PDS is engineered to create an elastomer, instead of the less cross-linked silicone gels or non–cross-linked silicone oils. Although 76% of particles are greater than 100 µm in diameter, **7% are less than 50 µm in diameter.** The smaller particles and possible intramuscular injection of the agent are responsible for migration of particles to the lungs, kidneys, brain, and lymph nodes demonstrated in animal models. Unlike Teflon paste, Macroplastique does not cause an intense local inflammatory response. In patients requiring open surgery after failed injection with Macroplastique, the injectable bolus was found encapsulated and easily removed without adherence to the ureter or bladder (Herz et al., 2001). Histologic examination of the bladder muscle biopsies and pelvic lymph nodes at the time of open surgery revealed a mild inflammatory reaction with no evidence of PDS particle migration in either the wall of the bladder or the draining lymph nodes.

The efficacy of PDS as a bulking agent for correction of reflux is well documented. Dodat et al. reported on the long-term outcomes of Macroplastique injections for correction of VUR (Dodat et al., 2004). Results in 590 refluxing ureters in 389 patients who were injected with a minimum follow-up of 5 years revealed a sustained success rate of 79.4%. Herz et al. demonstrated a reflux resolution rate of 81% after a single injection and 90% after a second injection with a 12-month follow-up (Herz et al., 2001).

The main advantage of PDS is that it is a permanent material that remains well encapsulated, causing minimal local inflammatory changes. Another report, however, draws attention to the development of a Macroplastique bolus calcification occurring in 2 of 31 children presenting with irritative lower urinary tract symptoms 30 and 36 months after injection. At the time of surgery, the calcified material was extracted after unroofing the overlying necrotic mucosa (Bae et al., 2010). Eyssartier et al. made similar observations (Eyssartier et al., 2012). These reports underscore the importance of long-term monitoring after the injection of foreign materials in growing children. Despite its demonstrated long-term track record, PDS has yet to achieve FDA approval for correction of VUR in the United States, possibly because of concerns regarding migration, particularly the presence of particles smaller than 80 µm and the negative connotations associated with silicone implants.

Dx/HA (Deflux) is formed of cross-linked dextranomer microspheres (80 to 250 µm in diameter) suspended in a carrier gel of stabilized sodium hyaluronate. Dx/HA is biodegradable, the carrier gel is reabsorbed, and the dextranomer microspheres are capsulated by fibroblast migration and collagen ingrowth. Dx/HA loses approximately 23% of its volume beyond 3 months of follow-up (Stenberg and Lackgren, 1995).

Deflux was first introduced by the Swedish group of Stenberg and Lackgren and received FDA approval in 2001 (Stenberg and Lackgren, 1995). Since then, several clinical reports from Europe and the United States have documented success rates ranging from 68% to 89% (Lackgren et al., 2001; Puri et al., 2003; Kirsch et al., 2004; Lavelle et al., 2005). The introduction of the double HIT by the Atlanta group has resulted in higher reflux resolution rates of 90% in 336 children (Kalisvaart et al., 2012).

In a long-term follow-up study by Lackgren et al., 68% of 221 children injected using the classic STING technique and followed for a mean of 5 years maintained grade 1 VUR or less at the last VCUG (Lackgren et al., 2001). No significant long-term adverse effects were noted. Other groups have, however, reported the risk for late-onset ureteral obstruction with Dx/HA (Rubenwolf et al., 2013; Christen et al., 2014; Papagiannopoulos et al., 2017). Salvage ureteral reimplantation after failed endoscopic correction with Dx/HA can be accomplished, usually without difficulty. The implant bolus is frequently observed in the periureteral space outside the bladder and is well encapsulated, with mild inflammatory changes (Sparks et al., 2011).

The appeal of Dx/HA is that it is a natural product that is easily administered without a ratcheted syringe through a smaller-gauged needle. It is currently the preferred agent for endoscopic correction in most centers; however, the durability of correction of VUR with Dx/HA remains to be proven.

Polyacrylate polyalcohol copolymer (PPC) (Vantris) is a new nonbiodegradable tissue-augmenting agent belonging to the family of acrylics described by Ormaechea in 2008. The particles of PPC are immersed in a glycerol and physiologic solution carrier (Ormaechea et al., 2008). The particles have a size of 300 µm and should therefore not migrate. PPC particles are encapsulated by fibrotic tissue giving little rise to inflammatory reactions. Initial results reported by Ormaechea and Chertin revealed high reflux resolution rates after one treatment (Ormaechea et al., 2010; Chertin et al., 2011). A recent multicenter survey found resolution rates of 98% (Kocherov et al., 2014). Warchol et al. found higher resolution rates for PPC than for Dx/HA in a comparative study, and in a recent follow-up study the success rate after PPC remained high even for high-grade reflux (Warchol et al., 2016, 2017). The length of follow-up in this study is sparsely described but reaches up to 4.5 years. Late-onset ureteral obstruction, however, remains a major concern offsetting the trade-off of higher resolution rates compared with other bulking agents (Ben-Meir et al., 2017; Warchol et al., 2017). PPC has not yet been approved by the FDA.

A number of other nonautologous and autologous substances are under development but have not yet been introduced to clinical practice.

Recurrence of Vesicoureteral Reflux After Endoscopic Correction

The true incidence of recurrent VUR after successful endoscopic correction with any specific material is difficult to determine because a repeat VCUG is not obtained beyond the initial negative study except in the context of a research protocol. Only a handful of series have reported long-term follow-up with repeat VCUG beyond the initial negative study. Chertin and Puri reported a 5% recurrence rate using Teflon paste with follow-up of up to 17 years (Chertin and Puri, 2002). In the Swedish Reflux Trial, 20% of previously successfully treated children had a recurrence after 2 years of follow-up (Holmdahl et al., 2010).

The higher recurrence rate with Deflux, an absorbable agent, is not unexpected. However, in the absence of UTI, the significance of confirming the long-term absence of VUR is less important. Furthermore, even if absorbable bulking materials were to lose volume or reabsorb completely over time, VUR resolution may be maintained by growth of the child and maturation of the UVJ. The injectable agent may just have bought time for this process to conclude. The implication of recurrent reflux in young adulthood for these patients is inadequately defined at the present time. More recent evidence suggests that children undergoing endoscopic correction with a preinjection history of multiple febrile UTIs, bladder and bowel dysfunction, and renal scarring are at a higher risk for recurrent infections and late recurrence of VUR despite initial negative VCUG (Sedberry-Ross et al., 2008).

Endoscopic correction of VUR is a reasonable alternative for children being considered for surgical correction; however, families should be informed of the varied success rates across centers and that outcomes may not be durable.

Megaureter

Definition

The term *megaureter* is a descriptive one denoting dilation of the ureter irrespective of cause. Originally coined by Caulk in 1923 as *megaloureter,* other synonyms in use include wide ureter and hydroureter and in general refer to a ureter that has a diameter ≥7 mm based on the studies of Cussen and Hellstrom, which defined the upper limit of the range of normal ureteral diameters in children up to 16 years of age as being 0.50 to 0.65 mm (Cussen 1967; Hellstrom et al., 1985). Etiology of megaureters is either primary, representing a condition intrinsic to the ureter itself, or secondary to bladder pathology, such as neurogenic bladder dysfunction, bladder outlet obstruction, and/or infection. **Megaureters have been subclassified into four categories based on causality: obstructed, refluxing, nonobstructed nonrefluxing, and refluxing with obstruction** (Smith, 1977; King, 1980). In circumventing the refluxing type, which is easily diagnosed and has been dealt with previously, distinguishing between obstructed megaureters and those that are nonobstructed nonrefluxing can be somewhat challenging. For as is the case with hydronephrosis, the mere presence of ureteral dilation, which at times can be quite alarming on imaging, does not necessarily indicate significant obstruction. **The challenge is in the balance between early identification and management of the obstructed ureters to prevent renal functional deterioration and to not consign ureters with balanced stable dilations to unnecessary intervention.**

Etiology, Occurrence, and Presentation

The pathophysiology of primary obstructed megaureters (POMs) has not been fully ascertained, but there is general agreement that obstruction results from the presence of an abnormal adynamic segment at the terminal end of the ureter near or at the UVJ. Absent or inefficient peristalsis at the UVJ leads to obstruction and upstream dilation. Fetal animal studies by Tanagho and Pirker have demonstrated that the ureteral muscular layers develop in a craniocaudal direction, leaving the juxtavesical part of the ureter to develop last, with maturation of this terminal part continuing postnatally (Tanagho, 1973; Pirker et al., 2007). This corresponds well with studies in human fetuses that showed a similar directional maturation with typical fetal circular muscular fibers first maturing to the double muscle layer of the full-term infant well past delivery, a fact that may explain transient dysfunction at the UVJ and the spontaneous resolution of some POMs with age (Matsuno et al., 1984; McLellan et al., 2002). Other studies point to the presence of excessive and abnormal collagen deposition at the narrow part of the ureter (Notley, 1968; Gosling and Dixon, 1978) or presence of a thick enveloping sleeve of muscle surrounding the muscle bundles of the terminal ureter (Dixon et al., 1998). Most recently, Kang demonstrated abnormalities in the interstitial cells of Cajal in POM cells whose primary function is related to smooth muscle contractility, pacemaker activity, and ultimately peristalsis (Kang et al., 2009).

The true incidence of POM is not known but is thought to average 10% to 23% of antenatally detected upper urinary tract dilations (Brown et al., 1987; Gokce et al., 2012). The anomaly has a predilection for boys and the left side. It is bilateral in 25% of cases and is associated with contralateral dysplasia or obstruction in 10% to 15% of cases (Joseph, 2007). Most POMs are detected by antenatal ultrasound screening, with the vast majority being asymptomatic. In an interesting paper from 1987 by Brown et al., the role of prenatal ultrasonography was documented in that the majority (79%) of patients with POM (constituting 23% of antenatally detected dilations) were detected antenatally as opposed to the pre-ultrasound era, when only 8% of patients presenting symptomatically and consequently found to have upper urinary tract dilation were diagnosed with POM (Brown et al., 1987; Rubenwolf et al., 2016). Symptoms when present include those of UTI, abdominal pain, and microscopic hematuria, even in the absence of infection. This is believed to result from the disruption of urothelial microvasculature caused by distention or calculi. In rare instances, previously undiagnosed patients can present with an abdominal mass, although this is more of a pre-ultrasound era feature in contrast with the very infrequent presentation with signs and symptoms of renal impairment currently (Shokeir and Nijman, 2000).

Surgical Indications

By historical account, it can be deduced that the majority of nonrefluxing megaureters run a benign course and resolve spontaneously within the first few years of life (Matsuno et al., 1984; Brown et al., 1987; McLellan et al., 2002; Shukla et al., 2005; Rubenwolf et al., 2016). This has been confirmed in a prospective observational study by Ranawaka et al., who showed that complete resolution and time to resolution were inversely related to ureteral diameter with minimal complications or febrile episodes during follow-up for those with a ureteral diameter <10 mm while maintained on antibiotic prophylaxis, and virtually none proceeded to surgery. On the other hand, patients with ureteral diameters >10 mm were more prone to complications such as recurring febrile UTIs, stone formation, and abdominal pain, with only 17% resolving completely and an overall 21% of them requiring surgical intervention (Ranawaka and Hennayake, 2013). Persistence of dilation therefore warrants continued close follow-up with periodic ultrasound examinations supplanted with functional studies when deemed necessary until resolution or stability of dilation is confirmed. The role of extended follow-up into early adulthood has also been advocated based on worsening of some previously stable megaureters at or beyond puberty (Shukla et al., 2005).

As a result, there has been a steady trend toward conservative management of patients with megaureters during the past 25 years. An increased understanding of the pathophysiology of this condition combined with advances in minimally invasive procedures has also shifted management in a more minimally invasive direction. **Surgery in the case of POM is to be considered when patients are symptomatic and have recurring UTIs, progressive unremitting dilation on ultrasonography, differential renal function <40%, and/or significant decreases in differential renal function of ≥ 5% on sequential “comparable” renal nuclear functional studies** (Farrugia et al., 2014). Several studies cite prolonged washout or drainage curves on diuretic renograms as being an indication to intervene, as prolongation of T½ is equated with significant obstruction. Relying on renographic washout curves as a measure of obstruction is, however, problematic and can be misleading, as it has been shown that washout curves in neonates and infants can be affected by many factors other than “restriction of flow”: renal function and the ability to respond to diuretic stimulation, hydration status, posture, distensibility and volume of the collecting system, in addition to matters related to procedural and technical aspects, such as the timing of diuretic administration and curve interpretation. Collectively, these variables limit the usefulness of drainage curves as has been documented in a study that reported false-positive results in up to 44% of renographies (O'Reilly, 1989; Shokeir and Nijman, 2000).

Surgical Management

Basic principles of megaureter correction are simple and straightforward; the surgical procedure can be quite demanding, however, and should be reserved for the pediatric urologist with experience in bladder and ureteral surgery and in whose hands favorable results can be achieved. **In summary, the stenotic distal part of the ureter is excised, and the megaureter is straightened and then tapered to facilitate reimplantation in a nonrefluxing fashion with an adequate length-to-diameter ratio of 5 : 1 so as to improve coaptation of the ureteral lumen whereby effective peristalsis and urine transportation is achieved** (Paquin, 1959). Several eponymous procedures have been described for ureteral remodeling and its reimplantation, and with time numerous modifications and refinements have emerged. **And as the laparoscopic and robotic envelope continues to be pushed, the same basic principles are increasingly being achieved by laparoscopic and robotic-assisted techniques, albeit at a limited number of centers**.

If prompt decompression of a POM is necessary, this can be achieved by nephrostomy tube diversion, however, nephrostomy tubes are difficult to maintain in infants for prolonged periods and carry the risk for leakage, infection, and displacement. A better temporizing option would in this case be distal cutaneous ureterostomy. This simple technique allows rapid decompression of the dilated and potentially infected system and allows a delay in definitive reconstruction, which is usually warranted in infants in whom incongruity between the small bladder and the severely dilated ureter does not allow for safe nonrefluxing reimplantation. Also there is a general reluctance to perform reimplantations in infants for fear of inducing bladder dysfunction, a claim that may be overstated according to a study by de Kort et al. (de Kort et al., 2002). The ureter can hence be approached through a small oblique inguinal incision, carried through muscle splitting dissection to the perivesical space (Fig. 42.25). The distal part of the dilated tortuous ureter is identified and picked up by nontraumatic forceps or a noncrushing Allis clamp. Peritoneal adhesions may have to be swept off using a pledget, and a vascular loop is then pulled under the ureter to allow atraumatic handling. The ureter can then be pulled out into the incision as a loop secured to the fascia with several absorbable monofilament 5-0 sutures, whereafter the fascia is approximated to the distended ureter with the same suture. The ureter can then be opened transversely and the edges everted and secured to the skin using 5-0 or 6-0 absorbable monofilament sutures. A drainage catheter can be left in situ for the first 24 to 48 hours to aid in drainage and decompression of the redundant dilated system. Because of the dimensions of the ureter, stenosis of the stoma is a rare occurrence (Rabinowitz et al., 1977; Kitchens et al., 2007). Another temporizing procedure in the infant that is gaining acceptance is that of internal diversion by means of a refluxing reimplantation. The dilated ureter is transected proximal to the stenotic terminal part and is anastomosed directly in a freely high-grade refluxing fashion whereby “dangerous” obstruction is converted into the “lesser evil” of VUR. Preliminary studies have shown promising results of this temporizing procedure, however, long-term outcomes with regard to effect of reflux on renal function are awaited (Lee et al., 2005; Farrugia et al., 2014; Kaefer et al., 2014; Babu, 2016).

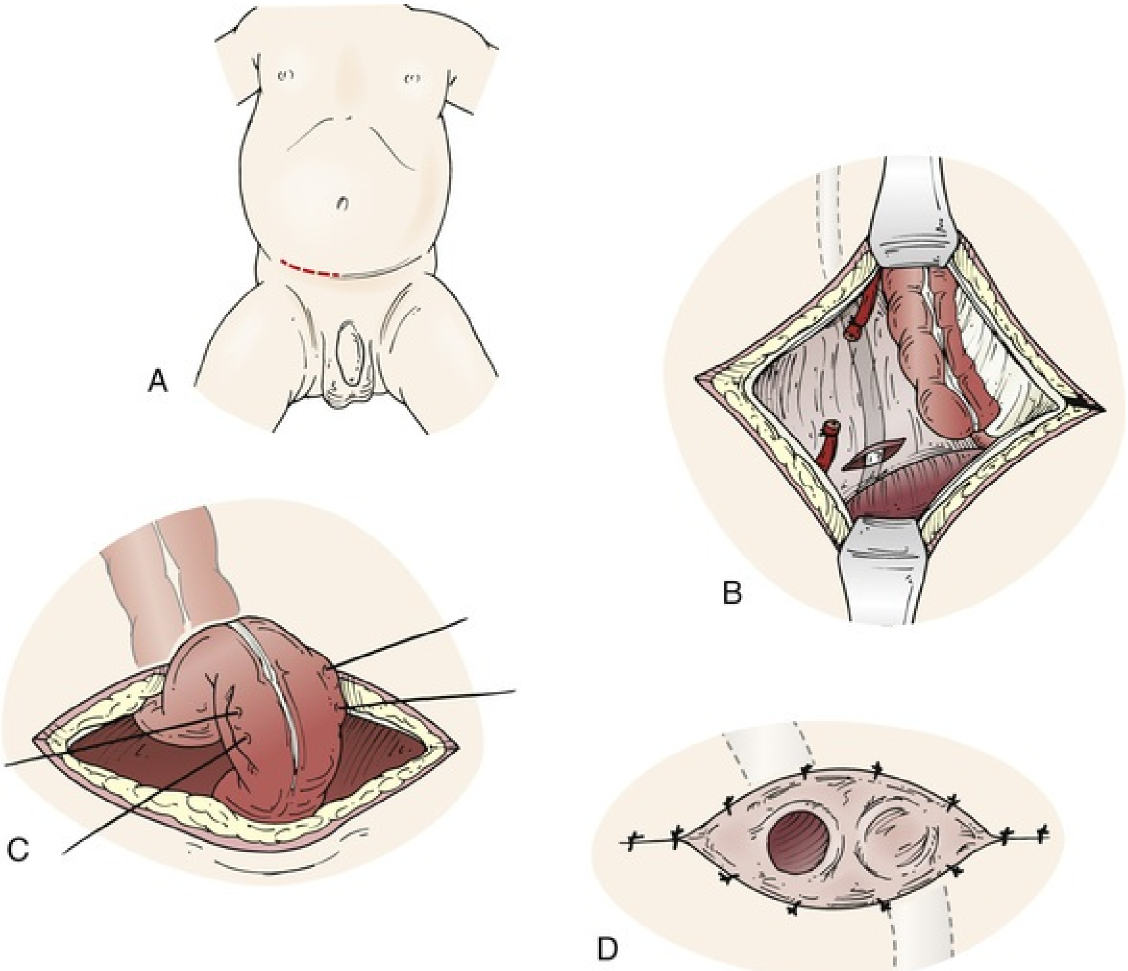

FIG. 42.25 Diversion with ureterostomy. (A) A small oblique or transverse inguinal incision is made. (B) Muscles are separated bluntly, and the perivesical space is accessed. The dilated tortuous ureter is identified, the

obliterated umbilical artery being divided and ligated if necessary. (C) The ureter is mobilized and brought out as a loop to the incision, where it is fixed to the fascia, and the incision is approximated to the ureteral wall. (D) The ureter is now opened, and the edges are everted and fixed to the skin with fine absorbable monofilament interrupted sutures.

Definitive reconstruction entails remodeling and reimplanting the ureter in a nonrefluxing fashion. The bladder is accessed through a low transverse Pfannenstiel incision, and the dilated ureter can then be mobilized into the bladder as shown previously (see Fig. 42.18A–E). Once completely mobilized within the bladder, the technique of reimplantation and remodeling must be decided on, as it dictates the next steps. In case of choosing an intravesical reimplant such as the Cohen cross-trigonal or the Politano-Leadbetter, work can be continued from within the bladder. **It is however advisable to move outside the bladder in cases of a very large ureter or to perform the whole dissection, transection, and remodeling of the ureter extravesically and proceed with an extravesical form of reimplantation, especially if the discrepancy between ureteral diameter and bladder is significant, so as to avoid excessive bladder dissection and creation of a very large hiatus in the trigone area** (Perovic, 1994).

Tailoring of the ureter can be achieved by one of two basic methods: plication or excisional tapering. With plication, the megaureter is imbricated or folded around an 8- or 10-Fr catheter depending on patient age. Ureteral redundancy is marked by brief placement of atraumatic Allis clamps around the ureter containing the medialized catheter. After removing the clamps, the Starr plication technique (Fig. 42.26) includes imbricating the redundant lateral edge of the dilated ureter by multiple interrupted 5-0 monofilament absorbable sutures in the Lembert fashion along the clamp impressions (Starr, 1979). In the Kalicinski plication (Fig. 42.27), a 6-0 monofilament absorbable suture is woven in a continuous fashion craniocaudally through the ureteral wall along the clamp impressions, thereby defunctionalizing the redundant lateral aspect, which, in turn, is folded back and fixed along the catheterized lumen with multiple 6-0 interrupted sutures (Kalicinski et al., 1977). In plication techniques, the blood supply to the ureter is preserved as the ureteral walls are kept intact, thereby decreasing the risk for ischemia and stenosis (Bakker et al., 1988). **Folding techniques are, however, only suitable for the moderately dilated ureter (<1.75 cm in diameter)** (Fretz et al. 2004) **as too big a diameter will result in a bulky remodeled ureter that is difficult to reimplant and significantly**

increases complications and failure rates (Parrott et al., 1990). In general, favorable results have been reported with folding techniques with success rates of 90% to 95% (Ehrlich, 1985; Perdzynski and Kalicinski, 1996; Daher et al., 1999; Fretz et al., 2004). Postoperatively stents in the form of baby feeding tubes or double pigtail catheters are left in situ for 7 days and 4 weeks, respectively, for drainage purposes. Follow-up pyelography via stentograms is not indicated at stent removal.

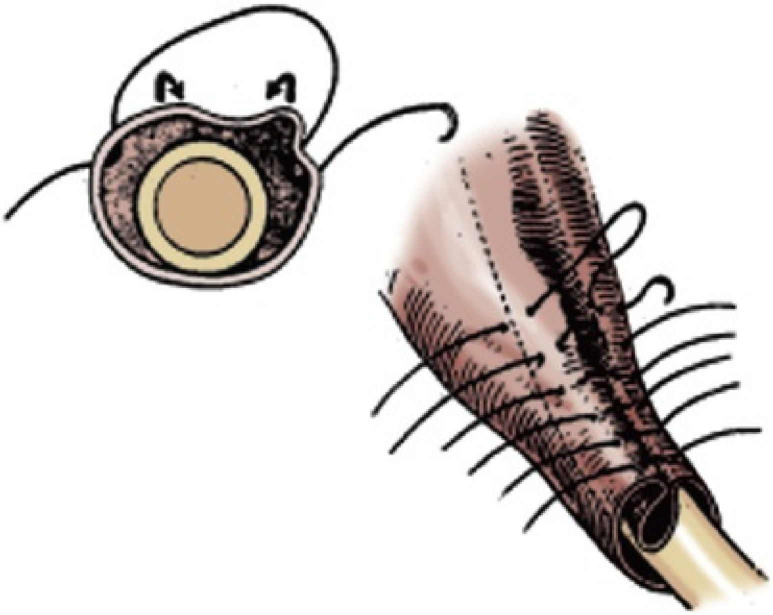

FIG. 42.26 Starr plication. Ureteral plication is performed over the appropriate catheter, with interrupted 5-0 monofilament absorbable sutures placed in Lembert fashion (after Starr). (From Keating MA, Retik AB. Management of failures of ureteroneocystostomy. In: McDougal WS, ed. *Difficult problems in urologic surgery*. Chicago, IL: Year Book; 1989).

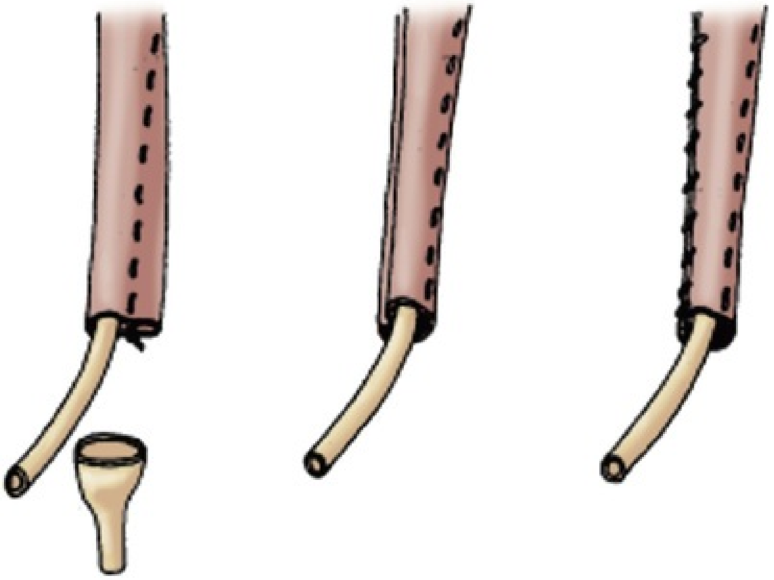

FIG. 42.27 Kalicinski folding technique. Ureteral folding technique. A running suture is longitudinally woven through the megaureter to create two lumens. This isolates the best-vascularized portion as a functional ureter (catheter within) and excludes redundancy. The redundant portion is then folded, and the two are tacked together with interrupted sutures.

Excisional tapering as described by Hendren was the forerunner for the later modifications of folding techniques, as it is believed and has been shown that excisional tapering may jeopardize ureteral vasculature with all its attendant complications (Hendren, 1969; Bakker et al., 1988; Whitmore and Ehrlich, 1988; Parrott et al., 1990). Nonetheless the Hendren procedure has its advantages, especially when dealing with massively dilated ureters that are not amenable to folding. The procedure (Fig. 42.28) follows the same principle steps of defining the redundant less vascular lateral part of the ureter around an 8- to 10-Fr catheter. Instead of folding, the excess ureteral tissue is excised and closed with a running locking 6-0 absorbable monofilament suture along the proximal two-thirds of the ureteral length to be remodeled. The distal third is closed by interrupted sutures of the same kind to allow for appropriate shortening of the ureter at reimplantation without violating the integrity of the running anastomosis (Hendren, 1969). The same postoperative regimen is followed as with the folding techniques. Athough success rates with this method have generally been excellent, exceeding 90% in many studies (Hendren, 1969; Parrott et al., 1990; DeFoor et al., 2004), refinements aimed at preserving vasculature by limiting excision to the mucosal and muscular parts of the redundant ureter, leaving behind the vascular-rich adventitial layers, may even improve on these outcomes by lowering the risk for ischemia (Ossandon et al., 2005). It is pertinent for all types of ureteral remodeling that tapering be gradual so as not to cause an abrupt change in ureteral caliber, which may cause a form of obstruction. After ureteral remodeling is completed, one can proceed with reimplantation in accordance with the same surgical principles of VUR reimplantation.

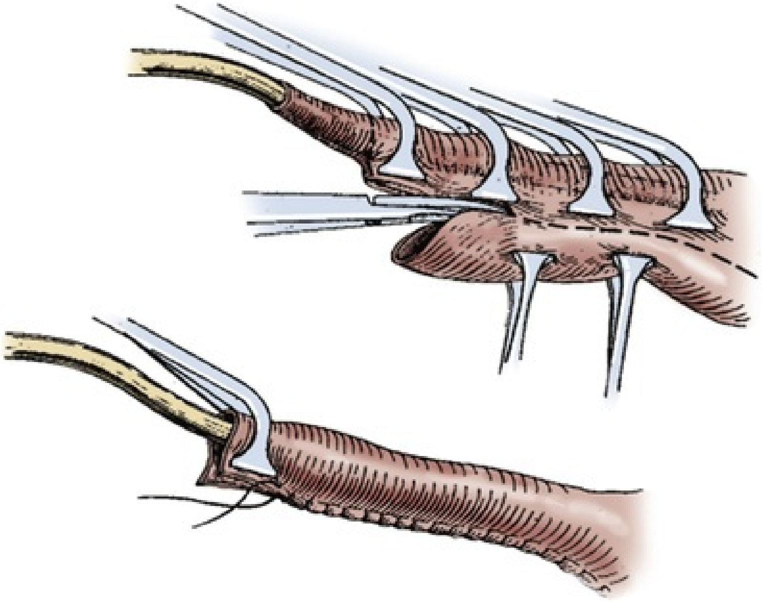

FIG. 42.28 Excisional tapering. Tapering is done over an 8-Fr red rubber catheter in infants or a 10-Fr catheter in older children and adults. After vascularity is defined, special atraumatic clamps are placed over the catheter. Baby Allis clamps help retract the portion of ureter to be resected, which is usually lateral. It is important not to resect too much ureter. Running 5-0 monofilament resorbable sutures are used to reapproximate the proximal two-thirds of the ureter. Its distal third is closed with interrupted sutures to allow for shortening.

Laparoscopic ureteral remodeling and reimplantation follow the same general principles set for open techniques. An increasing number of reports are demonstrating the feasibility and success of these minimally invasive techniques with excellent short- to medium-term outcomes fully comparable with those of open procedures (Abraham et al., 2012; Bi and Sun, 2012; Bondarenko, 2013). Extravesical reimplantations seem to dominate as technical limitations impede tapering from within the bladder (Abraham et al., 2012; Bondarenko, 2013), although a recent report has shown pneumovesical laparoscopic excisional tapering and transtrigonal reimplantation to be achievable (Bi and Sun, 2012).

Outcomes

In general, techniques of ureteral remodeling and reimplantation for POM have stood the test of time, producing excellent and durable results of over 90% success rates in several studies. Interestingly, outcomes for patients with POM have generally been more favorable than those for patients with refluxing megaureters, a fact that may be explained by histologic changes in the collagen to smooth muscle ratios in the UVJ of refluxing ureters, which may result in a stiffer, less compressible ureter (Lee et al., 1998; DeFoor et al., 2004). Poorer outcomes have also been reported in patients with dysfunctional voiding, neurogenic bladders, and other concomitant lower urinary tract pathology such as posterior urethral valves and obstructed flow (DeFoor et al., 2004; Carr and Casale, 2012). **The major reported complications are obstruction, vesicoureteric reflux, and persistent dilation.** Obstruction is initially managed by stenting as it is sometimes the result of postoperative edema; however, it can also be the result of ischemic stricturing especially after excisional tapering, in which case redo ureterneocystostomy is indicated with the attendant risks associated with revision surgery. Conservative management of vesicoureteric reflux is warranted, especially with the lower grades, as reflux has a tendency to resolve spontaneously in many cases. However, successful management with subureteric injection has been reported with minimal complication (DeFoor et al., 2004; Kitchens et al., 2006). Should subureteric injections fail, especially in cases of recurrent febrile UTIs, proceeding to revision surgery may be the only available option. A transureteroureterostomy may offer a valuable management option for unilateral cases in which there is severe ureteral scarring or concern regarding compromised blood supply.

Dilation and Stenting

Endoscopic dilation and stenting of the UVJ in POM has garnered increasing interest during the past decade or so. The method is less invasive than formal open or laparoscopic surgical intervention, with short- to medium-term success rates in the vicinity of 70% to 80% in most studies (Angerri et al., 2007; Carroll et al., 2010; Farrugia et al., 2011; Bujons et al., 2015; Capozza et al., 2015; Casal Beloy et al., 2018). The procedure is however not without complications; stent migration, infection, hematuria, and stone formation have been reported in up to 31% of cases in one series (Farrugia et al., 2011). Furthermore, the need for restenting, stenting by open surgical access in difficult cases, and ureteral injuries requiring emergent reimplantation may limit widespread use before long-term outcomes are documented (Carroll et al., 2010, Farrugia et al., 2011). In essence, the ureteral orifice of the POM is accessed endoscopically and dilated by a ureteral catheter or high-pressure balloon under fluoroscopic guidance until the indentation or waisting on the balloon disappears. Thereafter, a double pigtail catheter is left for 2 to 6 months before removal. Persistent dilation or renal function deterioration at follow-up has successfully been treated by restenting in some patients, and others have required reimplantation (Farrugia et al., 2014).

Key Points: Megaureter

- The term *megaureter* is a descriptive one denoting dilation of the ureter irrespective of cause.
- Megaureters have been subclassified into four categories based on causality: obstructed, refluxing, nonobstructed nonrefluxing, and refluxing with obstruction.
- The challenge is to prevent renal functional deterioration with either conservative or surgical treatment.
- Surgery is indicated for recurring UTIs, progressive unremitting dilation on ultrasonography, differential renal function <40%, and/or significant decreases in differential renal function of ≥5% on sequential “comparable” renal nuclear functional studies.
- During the surgical procedure, the stenotic distal part of the ureter is excised, and the megaureter is straightened and then tapered to facilitate reimplantation in a nonrefluxing fashion with an adequate length-to-diameter ratio of 5 : 1 so as to improve coaptation of the ureteral lumen whereby effective peristalsis and urine transportation is achieved.
- Most surgeons advocate temporary postoperative stenting.

Management of Pediatric Kidney Stone Disease

Gregory E. Tasian MD, MSc, MSCE, Lawrence A. Copelovitch MD

Kidney stone disease (nephrolithiasis) is a disorder of mineral metabolism characterized by acute symptomatic events that often recur. Nephrolithiasis affects 9% of the US population (Scales et al., 2012) and results in health care costs of more than $10 billion annually (Pearle et al., 2005), exceeding the treatment costs for prostate cancer and urinary tract infection (UTI) in women by more than 3 billion and 5 billion dollars, respectively (Khan et al., 2016). The prevalence of nephrolithiasis in the United States increased from 5% (1988 to 1994) to 9% (2007 to 2010) (Scales et al., 2012; Stamatelou et al., 2003). During this time, disproportionate increases in the incidence of nephrolithiasis of 5% to 10% per year have been reported for youth. **Among all age groups, the greatest increases in kidney stone disease have been observed among adolescents, particularly females** (Dwyer et al., 2012; Routh et al., 2010a, 2010b; Sas et al., 2010). The annual incidence of nephrolithiasis among girls 15 to 19 years of age increased from 75 per 100,000 in 1997 to 120 per 100,000 in 2012 (Tasian et al., 2016).

Although the gender gap has narrowed among adults (Scales et al., 2007), kidney stones are still more common among men (Scales et al., 2012). Among children and adolescents, however, girls have consistently been observed to have a higher frequency of stones compared with boys (Sas et al., 2010; Bush et al., 2010; Matlaga et al., 2010). The reasons for this are unclear, in part because of the lack of robust cohort studies in which the interaction of sex and putative stone risk factors could be explored. Nephrolithiasis among children and adolescents is most common among non-Hispanic Caucasians, followed by Hispanic Caucasians and African-Americans (Routh et al., 2010a, 2010b; Sas et al., 2010; Bush et al., 2010).

The increasing incidence of pediatric nephrolithiasis has resulted in increasing hospitalizations, emergency department visits, surgeries, and health care expenditures (Routh et al., 2010a, 2010b; Bush et al., 2010). Pediatric nephrolithiasis was estimated to cost the United States at least $375 million annually in hospital and emergency department care in 2010 (Wang et al., 2015). The true economic burden is higher when outpatient visits, medications, and diagnostic imaging are considered. In addition, indirect costs of missed work and lost wages by caregivers are substantial. Saigal estimated that management of nephrolithiasis resulted in an average of 19 hours per year of work loss, including 5 hours associated with ambulatory care visits (Saigal et al., 2005). The average work loss for an inpatient admission for stones was 48 hours. This increase in the incidence of nephrolithiasis in children has implications for future health care spending and for health services allocation and will increase the prevalence of what, for many, is a chronic condition associated with substantial pain and morbidity (Ljunghall and Danielson, 1984).

Given the emergence of nephrolithiasis as a pediatric disease, urologists will evaluate and treat a growing number of adult patients whose kidney stone disease began during childhood. To reduce the burden of disease across the lifespan, it is necessary that primary care providers and specialists understand the optimal evaluation and treatment strategies for children with nephrolithiasis. Stones should always be collected for analysis at the time of surgery or, when possible, when patients pass stones spontaneously. Knowledge of stone composition informs targeted therapy to decrease stone recurrence and also identifies those patients with rare, monogenic causes of kidney stones, such as cystinuria and primary xanthinuria. In adults, approximately 75% to 80% of stones are composed of predominantly calcium oxalate, 5% are predominantly calcium phosphate, 10% to 20% are struvite, and 5% are pure uric acid (Coe et al., 1992). **Contemporary analyses of stones that formed during childhood show a similar distribution, with calcium phosphate stones being slightly more common and uric acid stones being less common** (Kirejczyk et al., 2014). These differences may be caused, in part, by children's more alkaline urine. The notion that most stones that form during childhood are caused by rare genetic causes, inborn errors of metabolism, or infection is no longer true. Children with calcium oxalate stones have the same anatomic characteristics of the renal papillae as adults (Fig. 43.1). These include Randall's plaques, which are composed of hydroxyapatite (Evan et al., 2003, 2006), and are the platform on which most idiopathic calcium oxalate stones grow (see Fig. 43.1).

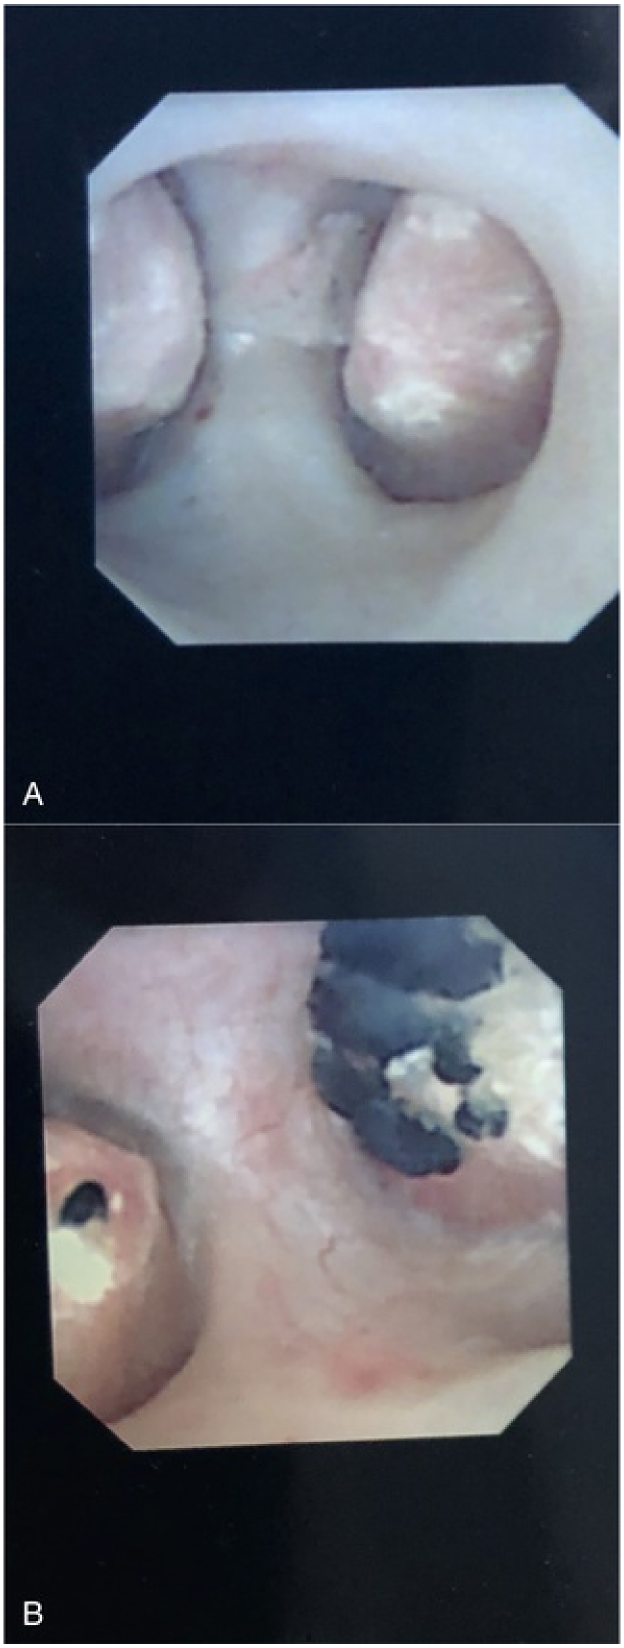

FIG. 43.1 Randall's plaques in a 16-year-old girl with calcium oxalate stones. Randall's plaques (A) appear as white deposits on the renal

papillae and are the sites on which idiopathic calcium oxalate stone attach (B).

Kidney stone disease that begins during childhood has a high risk for recurrence. Approximately 50% of patients who develop kidney stone disease during childhood will develop a recurrent stone within 3 to 5 years of the index stone (Lao et al., 2014; Tasian et al., 2017; Tekin et al., 2002), which is similar to or higher than rates reported for adults (Ljunghall and Danielson, 1984; Johnson et al., 1979). Contemporary studies of stone recurrence among pediatric patients have reported a higher probability of recurrence compared with historic studies (Pietrow et al., 2001; Diamond et al., 1989). These differences may be attributed to differential follow-up, inclusion of many patients with infectious stones (Diamond et al., 1989), and cohorts who don't reflect the current epidemiology of the disease. It is probable that many patients who have recurrent stone episodes during childhood will continue to recur during adulthood; however, there are no existing cohorts that allow for examination of the epidemiology of kidney stone disease across the lifespan.

Extrarenal Manifestations

In addition to a greater lifetime burden of disease as a result of recurrent stone events, exposure to ionizing radiation, and morbidity from surgical interventions, **patients who develop kidney stone disease during childhood are at risk for development of comorbidities such as decreased bone mineral density** (Letavernier et al., 2011; Asplin et al., 2006)**, chronic kidney disease** (Denburg et al., 2016)**, and heart disease** (Ristau et al., 2015). Using the well-characterized Health Professionals Follow-up Study, Nurses' Health Study I, and Nurses' Health Study II, Ferraro et al. (2013) reported that nephrolithiasis was associated with an 18% and 48% increased risk for coronary heart disease among older and younger women, respectively, after adjusting for known cardiovascular risk factors including hypertension, diabetes, hyperlipidemia, and BMI. No association was found for men. In addition to cardiac disease, nephrolithiasis has been associated with loss of kidney function (Alexander et al., 2012). In a Canadian cohort, one or more stone episodes was associated with an increased risk for chronic kidney disease, including a two-times greater risk for end-stage renal disease, compared with those without kidney stones (Alexander et al., 2012). The risk for chronic kidney disease was greater for patients with multiple stone episodes. In a population-based study in the United Kingdom, Denburg et al. (2016) reported similar findings; nephrolithiasis was associated with a 170% increased risk for incident chronic kidney disease (95% CI, 1.67 to 1.98). In the same dataset, Denburg et al. (2016) also demonstrated that nephrolithiasis was associated with a 42% increased risk for hypertension (95% CI, 1.35 to 1.51), which is very similar to the risk estimated by Madore et al. (1998) in the Health Professionals Follow-Up Study and Nurses' Health Study I and II. Although the causal pathway has not yet been elucidated, alterations in renal calcium and sodium handling may be important determinants of nephrolithiasis and hypertension (Obligado and Goldfarb, 2008). Nephrolithiasis has also been associated with an increased risk for fracture among children and adults. The greatest risk was estimated for those patients 10 to 19 years of age (Denburg et al., 2014). Decreased bone mineral density resulting from hypercalciuria and a negative calcium balance may underlie this association (Pietschmann et al., 1992; Jaeger et al., 1994; Cauley et al., 2005; Schwaderer et al., 2008). Accordingly, citrate and thiazides may help reduce the risk for osteoporosis as an adult (Schwaderer et al., 2014, 2011). Given that childhood is the critical period for acquisition of bone mass, identifying children at risk for low bone mineral density is essential to prevent fractures later in life. Although many studies of extrarenal manifestations of kidney stone disease were conducted among adult patients, these associations raise the concern that children may be at particular risk because early onset of nephrolithiasis may represent a more severe phenotype, and children have a long lifetime over which comorbid disease may develop.

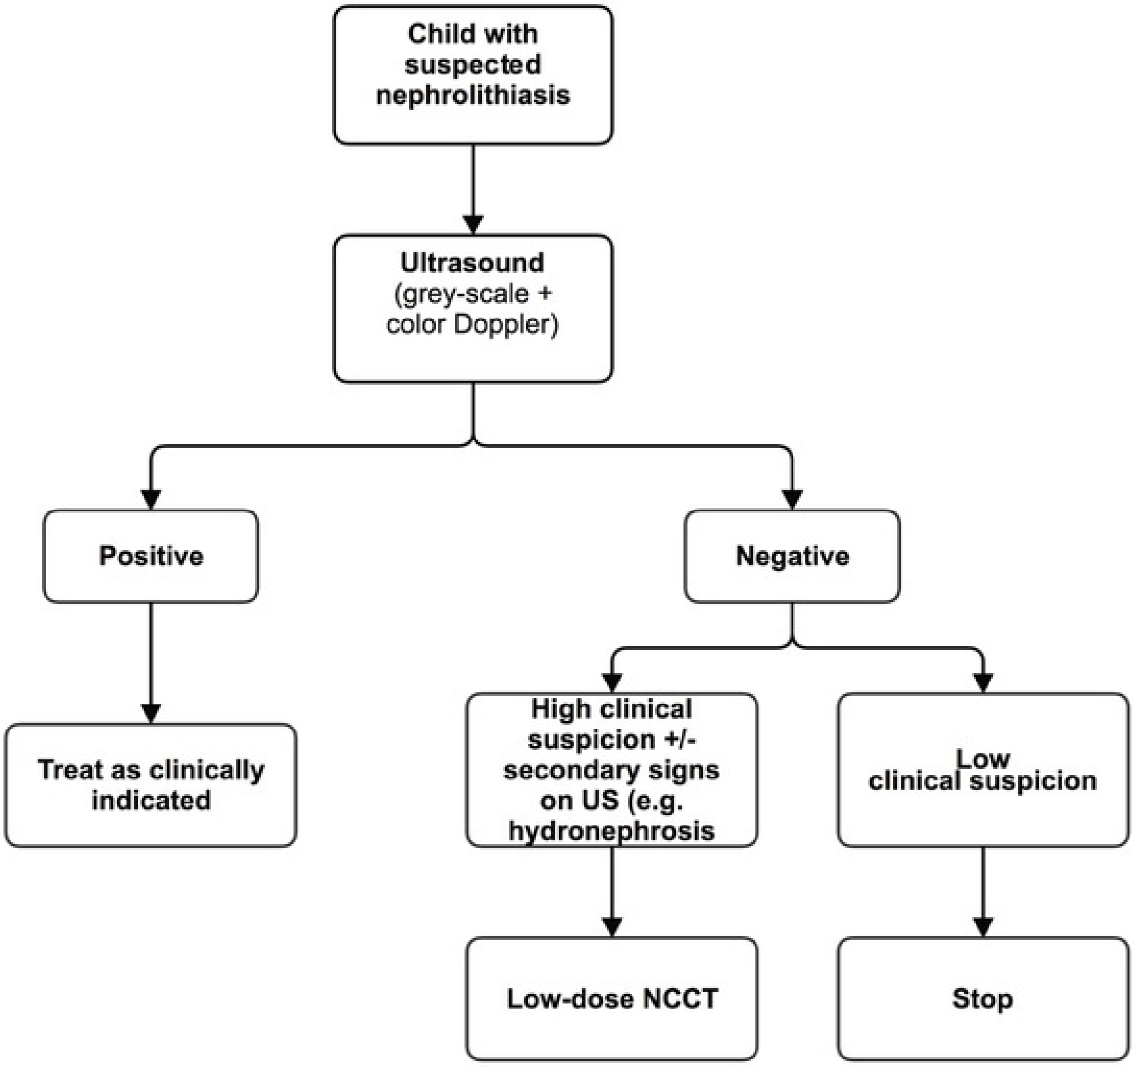
Key Points: Epidemiology of Kidney Stone Disease

- There has been a dramatic increase in the incidence of pediatric kidney stone disease, especially among adolescent girls.
- There is a female predominance of kidney stone disease in childhood and adolescence.
- Approximately 80% of kidney stones in children are composed predominantly of calcium oxalate, which is similar to adults, but calcium phosphate stones are slightly more common and pure uric acid stones are less common in children.
- Kidney stone disease is best conceptualized as a disorder of mineral metabolism and is associated with cardiovascular disease, chronic kidney disease, and decreased bone mineral density.

Evaluation

Child With Suspected Nephrolithiasis

The European Association of Urology and a technical paper by the American Urological Association support using ultrasound as the initial imaging study for children with suspected nephrolithiasis and obtaining a noncontrast computed tomography (CT) scan only for children with a nondiagnostic ultrasound in whom the clinical suspicion for stones remains high (Fig. 43.2; Türk et al., 2013, 2016; Fulgham et al., 2013). Additionally, the Image Gently Alliance began its campaign in 2007 to lower radiation exposure among children who need diagnostic imaging (Goske et al., 2008). Currently, it is not known whether these guidelines will reduce unnecessary CT utilization.



Child with suspected nephrolithiasis
Ultrasound (grey-scale + color Doppler)
Positive

FIG. 43.2 Diagnostic imaging algorithm for pediatric patients with suspected kidney or ureteral stones.

Although ultrasound is less sensitive and specific than CT (Johnson et al., 2011; Passerotti et al., 2009), ultrasound accurately identifies clinically significant kidney stones in children. The criteria for defining a stone on ultrasound are (1) hyperechoic focus in the renal papillae, calyces, or renal pelvis and (2) confirmatory twinkle artifact (Fig. 43.3). Twinkle artifact, an intense multicolor signal overlying stones generated by Doppler, improves the accurate detection of kidney stones (Masch et al., 2016; Gliga et al., 2017). Importantly, Doppler pulse repetition frequency (PRF) should be increased maximally to reduce noise from normal vascular flow and thereby improve accurate detection of stones (Tchelepi and Ralls, 2009). Although historically the presence of a posterior acoustic shadow was considered to be a necessary diagnostic criterion for defining a kidney stone on ultrasound, modern harmonic and spatial compounding ultrasound technology does not generate shadows as readily, particularly for stones less than 4 mm. **Ultrasound has >70% sensitivity and >95% specificity for detecting urinary tract stones, including stones located in the mid-ureter, which are poorly visualized on ultrasound** (Passerotti et al., 2009). Stones missed on ultrasound are often clinically insignificant (i.e., small in size or nonobstructing; Johnson et al., 2011; Passerotti et al., 2009). A recent cross-sectional study that incorporated twinkle artifact on Doppler ultrasonography reported 67% sensitivity, 97% specificity, 95% positive predictive value, and 79% negative predictive value for the detection of kidney stones. However, these patients in the study underwent ultrasound and then CT because of uncertainty of findings on ultrasound, which would decrease the sensitivity of ultrasound. The use of additional criteria such as renal resistive indices has been investigated in adults to help improve the diagnostic accuracy of ultrasound for nephrolithiasis (Dillman et al., 2011; Granata et al., 2009; Kielar et al., 2012). In addition, the resolution of modern ultrasound is higher than in many CT scans. This high resolution may lead to the detection of small foci (~2 mm) that twinkle and are too small for CT to detect. In our experience, these foci often reflect Randall's plaques with or without small attached stones (Fig. 43.4). These plaques are reflected as hyperdense papillae on CT (Deshmukh et al., 2015) but do not appear as distinct calculi on CT. The appearance of Randall's plaques or papillary deposits as distinct stones on ultrasound are consistent with studies that have demonstrated that ultrasound overestimates the size of stones by 1 to 2 mm.

FIG. 43.3 Ultrasonographic appearance of ureteral stone. A stone appears as an echogenic focus on gray-scale with confirmatory “twinkle artifact” on color Doppler. The pulse repetition frequency should be maximized when evaluating with Doppler. Stones smaller than 4 mm typically do not have an associated posterior acoustic shadow using modern ultrasound machines, transducers, and software packages.

FIG. 43.4 Ultrasonographic appearance of Randall's plaques. Randalls plaques (visualized on ureteroscopy in Fig. 43.1) have the same ultrasound characteristics as stones, although they typically are <4 mm.

Noncontrast CT has nearly 100% sensitivity and specificity to identify kidney stones. CT, however, delivers ionizing radiation, which is associated with an increased risk for malignancy (Katz et al., 2006). Although the attributable risk for cancer from a single CT scan performed for kidney stones is small (0.2% to 0.3% above baseline), the cumulative risk is higher for those undergoing repeated studies (Kuhns et al., 2011). Highlighting the cumulative risk for radiation exposure, Routh et al. (2010a, 2010b) analyzed 7921 children with kidney stones treated at hospitals within the Pediatric Hospital Inpatient Sample and observed that more than 2600 children underwent a median of two CT scans for a single kidney stone episode. Additionally, the risk may be higher in children than in adults because of a longer life expectancy and greater sensitivity of developing tissues to the effects of radiation. Computer-simulated dose reduction has been useful in determining diagnostic thresholds in children. When necessary (e.g., stone not visualized on ultrasound but with secondary signs of obstruction such as hydronephrosis), a low-dose noncontrast CT of the abdomen and pelvis should be performed. Compared with standard protocols, halving the dose to 40 mA for children weighing 50 kg or less does not significantly affect the diagnosis of pediatric renal stones (Karmazyn et al., 2009). Spielmann et al. (2002) reported excellent detection of calculi measuring between 2 and 8 mm using much lower amperage, with an almost threefold decreased estimated radiation dose compared with standard protocols.

Medical History and Physical Examination

A detailed medical history and physical examination are essential. Information pertaining to a family history of nephrolithiasis, hematuria, and chronic kidney disease can be essential in identifying patients at highest risk for inherited metabolic or genetic conditions such as cystinuria, primary hyperoxaluria, *CYP24A1* gene mutations, or Dent disease. **A focused dietary history with special emphasis on fluid and salt intake, vitamin (A, C, D) and mineral supplementation, and special diets (e.g. ketogenic diet) is indicated in every patient.** Obtaining a detailed medication history with special emphasis on corticosteroids, diuretics (furosemide, acetazolamide), protease inhibitors (indinavir), antibiotics (Tasian et al., 2018), and anti-epileptics (e.g., topiramate) can be instructive. Children with a history of prematurity, urinary tract abnormalities, UTIs, intestinal malabsorption, and prolonged immobility are all at increased risk for calculi formation. Detailed physical examination of the child for dysmorphic features (William syndrome), rickets (Dent disease, hereditary hypophosphatemic rickets with hypercalciuria), tetany (familial hypomagnesemia with hypercalciuria and nephrocalcinosis, autosomal dominant hypocalcemic hypercalciuria), or gout (hypoxanthine-guanine phosphoribosyltransferase deficiency, phosphoribosyl pyrophosphate synthetase superactivity) can be helpful.

Metabolic Investigations

Children with an identifiable metabolic abnormality have an up to fivefold increased risk for recurrence compared with children with no identifiable metabolic disorder (Pietrow et al., 2002). Consequently, all children should undergo a comprehensive metabolic evaluation. Whenever possible, analysis should begin with an infrared spectroscopy or radiograph diffraction analysis of a passed stone. If a cystine or struvite stone is found, the analysis will be diagnostic.

Serum and urine studies should be obtained in patients in whom stone analysis could not be performed or for those with either calcium or uric acid–based stones. A serum creatinine is essential to evaluate for possible acute kidney injury or chronic kidney disease. Serum calcium, phosphorous, bicarbonate, magnesium, and uric acid levels are effective in screening for hypercalcemia/hypocalcemia-associated calculi (see Urinary Metabolic Abnormalities later in this chapter and Table 43.1 for diagnostic evaluation characteristics of rare stones), hyperuricemia/hypourcemia, and genetic conditions associated with normocalcemic hypercalciuria including hereditary hypophosphatemic rickets with hypercalciuria, Bartter syndrome, distal renal tubular acidosis (dRTA), and familial hypomagnesemia with hypercalciuria and nephrocalcinosis. Unlike in adults, primary hyperparathyroidism is rare in children, and an intact parathyroid hormone level is not a universally accepted part of the initial evaluation unless there is evidence of hypercalcemia and hypophosphatemia. A 25-hydroxyvitamin D level should be evaluated in hypercalcemic and or hyperphosphatemic patients with a relevant history of exposure. Rarely biallelic loss of function mutations in the *CYP24A1* gene result in the loss of peripheral catabolism of vitamin D and persistently high levels of 1,25-dihydroxyvitamin D, which can mimic vitamin D intoxication. A ratio of

24,25 dihydroxyvitamin D to 25 hydroxyvitamin D (normal <25 to 30) may be a useful screen and should be considered in children with hypercalcemia and associated hypercalciuria in whom other causes have been excluded. Finally, a spot urine β_2-microglobulin or retinol-binding protein (low–molecular-weight protein) is a useful screening test for Dent disease and should be considered in males if there are recurrent calcium-based calculi in the setting of proteinuria or a family history of renal failure, focal segmental glomerulosclerosis, or recurrent calculi.

TABLE 43.1

When to Suspect Rare Inherited Metabolic or Genetic Conditions as a Cause of Nephrolithiasis in Children

---

HISTORY/PHYSICAL EXAMINATION	**CONDITION(s)**
History of polyhydramnios	Bartter syndrome
Growth failure/failure to thrive	Distal renal tubular acidosis
Rickets	Hereditary hypophosphatemic rickets with hypercalciuria, distal renal tubular acidosis, Dent disease
Ocular abnormalities	Familial hypomagnesemia with hypercalciuria and nephrocalcinosis
Tetany/seizures	Familial hypomagnesemia with hypercalciuria and nephrocalcinosis
Gout	Hypoxanthine-guanine phosphoribosyltransferase deficiency, phosphoribosyl pyrophosphate synthetase superactivity
Family history of renal disease or nephrocalcinosis	Cystinuria, primary hyperoxaluria, Dent disease
LABS	
Elevated serum creatinine	Dent disease, cystinuria, primary hyperoxaluria
Hypercalcemia/hypocalcemia	Biallelic *CYP24A1* mutations/autosomal dominant hypocalcemic hypercalciuria
Hypokalemia	Distal renal tubular acidosis/Bartter syndrome
Acidosis/alkalosis	Distal renal tubular acidosis/Bartter syndrome
Hyperuricemia/hypouricemia	Hereditary renal hypouricemia/hypoxanthine-guanine phosphoribosyltransferase deficiency, phosphoribosyl pyrophosphate synthetase superactivity
Hypomagnesemia	Familial hypomagnesemia with hypercalciuria and nephrocalcinosis

Proteinuria	Dent disease
Abnormal urinary crystals	Cystinuria
IMAGING	
Nephrocalcinosis	Hereditary hypophosphatemic rickets with hypercalciuria, distal renal tubular acidosis, Dent disease, Familial hypomagnesemia with hypercalciuria and nephrocalcinosis, Bartter syndrome
Radiolucent stones	Uric acid, cystine, or xanthine calculi

A 24-hour urine collection should be analyzed for calcium, oxalate, uric acid, sodium, citrate, creatinine, volume, pH, and cystine (cyanide-nitroprusside screening test). Results must be evaluated with respect to weight, body surface area, or creatinine to be properly interpreted in children. Urine creatinine excretion (normal 15 to 25 mg/kg/day for adults) is useful in assessing the adequacy of the urine collection. Supersaturations for calcium oxalate, calcium phosphate, and uric acid can be calculated from computer models based on the results of the urine collection. There is ongoing controversy as to whether a single 24-hour urine collection at the time of diagnosis is sufficient for proper evaluation (Castle et al., 2010) or whether two separate collections yield a greater number of specific diagnoses (Parks et al., 2002). Several commercial companies offer these 24-hour urine stone chemistry profiles. Although less precise, when children are not yet toilet trained, the evaluation may be performed by measuring the ratio of calcium, uric acid, citrate, and oxalate to creatinine in a random spot urine sample (Table 43.2). Repeat urine testing should be performed several weeks to months after a change in diet or after the initiation of a medication. Microscopic urinalysis for crystalluria is generally not diagnostic unless hexagonal crystals (cystine) or coffin lid–shaped triple phosphate crystals (struvite) are observed.

TABLE 43.2

Normal Values for Urinary Solute Excretion

METABOLITE	AGE	SPOT (mg/mg)	24-HOUR INDEXED (ALL AGES)	24-HOUR TOTAL EXCRETION
Calcium	0–6 months 7–12 months	<0.8 <0.6 <0.21	<4 mg/kg	Male: <250 mg/d Female: <200 mg/d

	>24 months			
Oxalate	0–6 months 7–24 months 2–5 years 5–14 years >16 years	<0.26 <0.11 <0.08 <0.06 <0.03	<50 mg/1.73 m^2 BSA	20–40 mg/day
Citrate	0–5 years >5 years	>0.2–0.42	Male: >180 mg/g creatinine Female: >300 mg/g creatinine	Male: >450 mg/d Female: >550 mg/d
Cystine	>6 months	<0.075	<50 mg/1.73 m^2 BSA	Male: <0.8 g/d Female: <0.75 g/d
Uric acid	>2 years	0.56 mg/dL GFR	<815 mg/1.73 m^2 BSA	

Urinary Metabolic Abnormalities

Hypercalciuria

Hypercalciuria is found in approximately 30% to 50% of stone-forming children (Milliner and Murphy, 1993; Stapleton et al., 1987). Hypercalciuria is not a single entity but rather a condition associated with many causes. The most common cause in both children and adults is idiopathic hypercalciuria. Idiopathic hypercalciuria is defined as hypercalciuria that occurs in the absence of hypercalcemia in patients in whom no other cause can be identified. The gene (or genes) responsible for familial idiopathic hypercalciuria have not been identified, but they appear to be transmitted in an autosomal dominant fashion with incomplete penetrance. Approximately 4% of asymptomatic healthy children demonstrate evidence of idiopathic hypercalciuria (Kruse et al., 1984), and 40% to 50% of those children have a positive family history of urolithiasis (Coe et al., 1979). **Hypercalciuria is formally defined as calcium excretion of greater than 4 mg/kg/day in children older than 2 years of age. In many**

children, a 24-hour urine collection is not practical, and a urine calcium/creatinine ratio is used to estimate daily calcium excretion. In school-age children, a calcium/creatinine ratio of 0.21 mg/mg or less is considered normal, although calcium excretion is higher for younger children. See Table 43.2 for reference values for urine chemistries.

When hypercalciuria is observed, several conditions must be excluded before establishing a diagnosis of idiopathic hypercalciuria. By definition, the patient should be normocalcemic. In hypercalcemic hypercalciuric patients, the possibility of hyperparathyroidism, biallelic *CYP24A1* mutations, and hypervitaminosis D should be investigated, and, when clinically indicated, a diagnosis of prolonged immobilization, sarcoidosis, malignancy, juvenile idiopathic arthritis, corticosteroid excess, adrenal insufficiency, or William's syndrome should be considered. Children with hypocalcemic hypercalciuria should be evaluated for hypoparathyroidism and autosomal dominant hypocalcemic hypercalciuria (gain-of-function mutation in the calcium-sensing receptor). Although the vast majority of normocalcemic hypercalciuric patients will ultimately be diagnosed with idiopathic hypercalciuria, it is critical during the initial evaluation to consider and exclude other associated conditions such as prematurity, diuretic exposure (furosemide, acetazolamide), anticonvulsant usage (topiramate), the ketogenic diet, Dent disease, Bartter syndrome, familial hypomagnesemia with hypercalciuria and nephrocalcinosis, dRTA, hereditary hypophosphatemic rickets with hypercalciuria, and possibly medullary sponge kidney.

Hyperoxaluria

Oxalate is an end product of the metabolic pathways for glyoxylate and ascorbic acid and is primarily excreted by the kidneys. The vast majority (80% to 85%) of daily urinary oxalate excretion is derived from normal metabolic homeostasis, and the remainder (10% to 15%) is from dietary intake. Daily urine oxalate excretion is generally less than 40 mg/day/1.73 m^2 of body surface area. The impracticality of performing 24-hour urine collections in very young patients requires the use of a random urine oxalate/creatinine ratio, which can be used to estimate oxalate excretion (see Table 43.2). Increased urinary oxalate excretion may be caused by an inherited metabolic disorder (primary hyperoxaluria) or, more commonly, as a secondary phenomenon caused by increased oxalate absorption or excessive intake of oxalate precursors.

Primary Hyperoxaluria

Primary hyperoxaluria (PH) types 1, 2, and 3 are relatively rare autosomal recessive disorders of endogenous oxalate production. Overproduction of oxalate by the liver causes excessive urinary oxalate excretion with resultant nephrocalcinosis and nephrolithiasis. The calcium oxalate deposition results in progressive chronic kidney disease, however the clinical presentation can vary from end-stage renal failure in the neonate to occasional stone passage into adulthood. As a result of this variability, the diagnosis is often overlooked and may be realized only after the loss of a transplanted kidney (Spasovski et al., 2010).

PH1 is caused by mutations in the *AGXT* gene that result in a functional defect of the hepatic peroxisomal enzyme alanine-glyoxylate aminotransferase (AGT). The deficit leads to accumulation of glyoxylate, glycolate, and oxalate in the urine. Importantly, pyridoxine is an essential cofactor for proper AGT activity and, rarely, profound vitamin B_6 deficiency can mimic PH1. PH type 2 is caused by mutations in the *grhpr* gene, with resultant deficient glyoxylate reductase-hydroxypyruvate reductase (GRHPR) enzyme activity causing excessive amounts of oxalate and L-glyceric acid to be excreted by the kidney (Hoppe et al., 2009). PH2 is somewhat milder compared with PH1 but is not benign. Recently, a third variant, PH3, has been described with mutations in the *HOGA1* gene (Belostotsky et al., 2010; Monico et al., 2011). *HOGA1* encodes a mitochondrial 4-hydroxy-2-oxoglutarate aldolase that catalyzes the fourth step in the hydroxyproline pathway (Monico et al., 2011). If urinary oxalate levels are noted to be elevated on a 24-hour urine collection, the diagnosis of PH1, 2, and 3 can be evaluated by measuring the urinary concentrations of glycolate (elevated in PH1), glycerate (elevated in PH2), and 4-hydroxy-2-oxoglutarate (elevated in PH3). Notably, increased concentrations of oxalate with normal concentrations of glycolate, glycerate, and 4-hydroxy-2-oxoglutarate is highly suggestive of secondary hyperoxaluria (see later).

Secondary Hyperoxaluria

In secondary hyperoxaluria, there is either dietary exposure to large amounts of oxalate (or oxalate precursors), or here is an underlying disorder that causes increased absorption of dietary oxalic acid from the intestinal tract. **Gastrointestinal absorption varies inversely with dietary calcium intake,**

and, as a result, calcium-deficient diets may increase oxalate absorption and hyperoxaluria (Polinsky et al., 1987). Oxalate is a by-product of ascorbic acid metabolism, and high doses of vitamin C have also been associated with hyperoxaluria. Increased dietary absorption is usually characterized by fat malabsorption or a chronic diarrheal disorder. Among secondary causes of hyperoxaluria, those attributable to gastrointestinal disease are inflammatory bowel disease, celiac disease, exocrine pancreatic insufficiency (cystic fibrosis), biliary tract disease, and small bowel resection/short bowel syndrome. The causal pathway is the presence of free fatty acids that bind calcium in the intestinal lumen resulting in more unbound oxalate that is free to be absorbed.

Hypocitraturia

Citrate is normally present in the urine and regulated through a process of both absorption and metabolism at the level of the proximal tubule. **Hypocitraturia is generally defined as a citrate-to-creatinine ratio of <128 mg/g in males and <300 mg/g in females on a 24-hour collection. Intracellular acidosis of the proximal tubule, caused either by metabolic acidosis or hypokalemia results in increased citrate absorption in the proximal tubule and resultant hypocitraturia.** The ketogenic diet, certain medications (topiramate, acetazolamide), dRTA, and chronic diarrhea are commonly associated with hypocitraturia. Given that an incomplete dRTA can occur in the absence of an overt systemic acidosis or hypokalemia, the condition can often be overlooked in the face of hypocitraturia if provocative acid-load testing is not readily available. In spite of these known associations, most cases of hypocitraturia are idiopathic, although a diet rich in animal protein and low in vegetable fiber and potassium seems to promote lower citrate excretion (Hess et al., 1994; Kok et al., 1990).

Cystinuria

Cystinuria is an autosomal recessive disorder caused by mutations in either the *SLC3A1* or *SLC7A9* gene, resulting in disordered amino acid transport in the proximal tubule (Ettinger et al., 1997). It is characterized by lack of reabsorption of cystine and the dibasic amino acids lysine, ornithine, and arginine. Normal individuals excrete <60 mg of cystine/day/1.73 m^2 of body surface area, whereas patients who are homozygous for cystinuria often excrete >400 mg/day/1.73 m^2 of body surface area (Coward et al., 2003). Patients typically present with renal colic and stones in the second or third decade of life;

however, they may present as early as infancy with staghorn calculi. The poor solubility of cystine in the urine causes precipitation in the collecting system which, if left untreated, usually results in recurrent episodes of calculi and long-term risk for renal failure. Associated UTIs may occur, and combined cystine/struvite calculi have been observed (Evans et al., 1982).

Hyperuricosuria

Uric acid excretion is greater in children than in adults, with the highest urinary fractional excretion (Fe) found in neonates (Fe 30% to 50%) and levels reaching adult values (Fe 8% to 12%) in adolescence (Cameron et al., 1993). Interestingly, in spite of the higher uric acid excretion observed in children, uric acid nephrolithiasis is rather rare in childhood, accounting for <5% of all renal calculi. Epitaxy, in which the presence of uric acid promotes calcium oxalate crystallization, may be found in patients with hyperuricosuric calcium oxalate nephrolithiasis (Coe, 1978). Epitaxy is the process by which the crystal base of one material allows the growth of a second mineral that it is in the same crystalline orientation. Hyperuricosuria is defined as >815 mg/day/1.73 m^2 of body surface area. When adjusted for glomerular filtration rate (GFR), relative uric acid excretion is fairly constant after 2 years of age (see Table 43.2). In children who are not yet toilet trained but are older than 2 years of age, hyperuricosuria can be defined as >0.56 mg/dL of GFR on a spot urine collection. This value may be calculated with the following equation:

$$\text{Urine uric acid (mg/dL)} \times \text{Plasma creatinine (mg/dL)}/ \\ \text{Urine creatinine (mg/dL)}.$$

Hyperuricosuria in the setting of low urinary pH is the greatest risk factor for uric acid stone formation. Hyperuricosuria associated with significant hyperuricemia is usually associated with inherited disorders of purine metabolism (hypoxanthine-guanine phosphoribosyltransferase deficiency, phosphoribosyl pyrophosphate synthetase superactivity), lymphoproliferative disorders, or polycythemia. Rarely, a condition known as hereditary renal hypouricemia characterized by low serum uric acid, hyperuricosuria, nephrolithiasis, and exercise-induced acute renal failure has been observed. Mutations in either the *SLC22A12* or *SLC2A9* genes, both of which encode urate transporters expressed in the proximal tubule, are known to be causative

(Ettinger et al., 1997). Other causes of hyperuricosuria include excessive purine intake (animal protein, anchovies, mussels), hemolysis, uricosuric medications (probenecid, salicylates, losartan), cyanotic congenital heart disease, melamine toxicity, and idiopathic (familial).

Key Points: Evaluation of Children With Kidney Stone Disease

- Children with an identifiable metabolic abnormality have an increased risk for stone recurrence.
- All children should undergo a comprehensive initial evaluation including a 24-hour urine collection for calcium, oxalate, uric acid, sodium, citrate, creatinine, volume, pH, and cystine.
- Idiopathic hypercalciuria is found in approximately 30% to 50% of stone-forming children.
- Hypocitraturia, hyperoxaluria, hyperusicosuria, and cystinuria remain important causes of childhood nephrolithiasis and need to be identified.

Management of Children and Adolescents With Kidney and Ureteral Stones

Medical Expulsion Therapy

Management options in pediatric patients with a ureteral stone include observation with pain control, medical expulsion therapy (MET), and surgery. MET is the use of α-blockers or, less commonly, calcium-channel blockers to facilitate passage of a ureteral stone. The mechanism for MET in increasing stone passage is that type 1a and 1d α-receptors are found in high concentrations in the smooth muscle of the distal one-third of the ureter and at the ureterovesical junction. Spontaneous stone passage without MET is higher among older patients and for smaller (especially less than 5 mm) and distal ureteral stones (Pietrow et al., 2002; Dangle et al., 2016). Although the greatest number and highest-quality studies of the efficacy and effectiveness of MET have been performed in adult patients, the weight of the evidence that indicates that α-blockers increase stone passage has led to the use of both in the pediatric population (Hollingsworth et al., 2006). Blockage of these receptors leads to dilation of the ureter and, presumably, increased passage of ureteral stones. To date, there are only four small, poor-quality randomized controlled trials of α-blockers for children with distal ureteral stones less than 12 mm, which generally demonstrated that α-blockers improved stone passage (Aydogdu et al., 2009; Mokhless et al., 2012; Aldaqadossi et al., 2015; Erturhan et al., 2013). Erturhan reported a significantly higher stone expulsion rate, reduction in pain, and shorter time to stone passage among patients receiving doxazosin (71%) than controls (29%) (Erturhan et al., 2013). Similarly, in the most recent trial, Aldaqadossi et al. reported 87% of children treated with tamsulosin (0.4 mg) passed stones compared with 63% of children treated with analgesics alone ($p = 0.025$). This study also reported a reduced mean time to stone expulsion in the tamsulosin group compared with the analgesic cohort (7.7 vs. 18.0 days; $p < 0.001$). In addition, a multi-institutional retrospective cohort study demonstrated that tamsulosin was associated with higher stone passage (56%) compared with those treated with analgesics alone (44%) (Tasian et al., 2014). These results were pooled in a systemic review and meta-analysis, which demonstrated that

MET with an α-blocker was associated with increased odds of stone passage compared with placebo or analgesic alone (OR 2.21, 95% CI, 1.40 to 3.49) (Velazquez et al., 2015). Overall, tamsulosin was safe in children despite its off-label use, with only three patients reporting mild nasal congestion and no patients stopping treatment secondary to side effects (Mokhless et al., 2011; Aldaqadossi et al., 2015). **The AUA and Endourological Society Guideline for the surgical management of urinary stones recommends that pediatric patients with uncomplicated ureteral stones ≤10 mm should be offered “observation with or without MET using alpha-blockers”** (Assimos et al., 2016a). This recommendation is categorized as moderate with a grade B level of evidence based on the RCTs described earlier. The guideline states that parents should be informed that the use of α-blockers is off-label and that the maximum duration of MET is unknown but should not exceed 6 weeks. Whereas α-blockers seem to be most effective for adults with ureteral stones greater than 5 mm (Ye et al., 2018), the size of the stone for which α-blockers provide the greatest benefit for pediatric patients is unknown.

Surgical Management

Up to 60% of children with kidney or ureteral stones require surgery (Routh et al 2010a, 2010b; Dangle et al., 2016; Tasian et al., 2014). However, among ten major areas in kidney disease, kidney stones have the fewest proportion of citations that are randomized controlled trials, demonstrating both the difficulty in completing randomized trials for nephrolithiasis and indicating the need for high-quality evidence to inform clinical practice (Strippoli et al., 2004). Despite the increasing incidence of pediatric nephrolithiasis, the comparative effectiveness of surgical interventions for pediatric patients with kidney stones is particularly unclear, and the evidence for or against any given surgery is especially poor. **As for adults, surgical options for pediatric patients include ureteroscopy (URS), shock wave lithotripsy (SWL), and percutaneous nephrolithotomy (PCNL), all of which require anesthesia and, traditionally, radiation exposure** (Routh et al 2010a, 2010b). A recent review reported stone clearance ranging from 70% to 97% for PCNL, 85% to 88% for URS, and 80% to 83% for SWL; however, the indications for surgery, methods of ascertaining residual fragments, and consideration of repeat procedures varied (Hernandez et al., 2015). Open stone surgery such as nephrolithotomy is rarely used in the contemporary era. Although historically most stones in children were treated with SWL, miniaturization and improvement in the optics of endoscopy resulted in increases in URS and PCNL utilization (Long and Srinivasan, 2015; Salerno et al., 2013). Endoscopic techniques initially utilized in adult populations have been increasingly utilized for children and adolescents as technologic advances have produced smaller, more flexible equipment. Introduction of flexible and smaller ureteroscopes have enabled treatment of proximal ureteral and renal stones, primarily for stones less than 15 to 20 mm.

In 2016, the American Urological Association and the Endourological Society published guidelines for the surgical management of kidney stones (Table 43.3) (Assimos et al., 2016a, 2016b). Of the 90 recommendations, only eight addressed children. Of the eight pediatric-specific recommendations, none were guided by level A evidence and four were based on expert opinion alone. For example, the recommendation for either URS or SWL for children with renal stones ≤2 cm was based on small, single-center studies, and the underlying evidence was noted to be of "low certainty." In addition, based only on expert opinion, either PCNL or SWL were recommended for children with stones greater than 2 cm. However, this recommendation is not consistent with the poor stone clearance of SWL for large stones among adults and contradicts the same guideline's recommendation for PCNL and against SWL for adults with stones greater than 2 cm. In response to this knowledge gap, the 2017 National Urology Research Agenda prioritized studies of pediatric patients with kidney stones (Ellison et al., 2018; Penniston et al., 2007, 2017).

TABLE 43.3

2016 American Urological Association and Endourological Society Recommendations for the Surgical Management of Urinary Stones for Pediatric Patients

RECOMMENDATION	STRENGTH OF RECOMMENDATION	LEVEL OF EVIDENCE
In pediatric patients with uncomplicated ureteral stones <10 mm, clinicians should offer observation with or without medical expulsive therapy using α-blockers.	Moderate: Net benefit or harm moderate	B: Moderate certainty
Clinicians should offer URS or SWL for pediatric patients with ureteral stones who are unlikely to pass the stones or who failed observation and/or MET, based on patient-	Strong: Net benefit or harm substantial	B: Moderate certainty

specific anatomy and body habitus.		
Clinicians should obtain a low-dose CT scan on pediatric patients before performing PCNL.	Strong: Net benefit or harm substantial	C: Low certainty
In pediatric patients with ureteral stones, clinicians should not routinely place a stent before URS.	Panel consensus, based on members' clinical training, experience, knowledge, and judgment for which there is no evidence.	Expert opinion
In pediatric patients with a total renal stone burden ≤20 mm, clinicians may offer SWL or URS as first-line therapy.	Moderate: Net benefit or harm moderate	C: Low certainty
In pediatric patients with a total renal stone burden >20 mm, both PCNL and SWL are acceptable treatment options. If SWL is utilized, clinicians should place an internalized ureteral stent or nephrostomy tube.	Panel consensus, based on members' clinical training, experience, knowledge, and judgment for which there is no evidence.	Expert opinion
In pediatric patients, except in cases of coexisting anatomic abnormalities, clinicians should not routinely perform open/laparoscopic/robotic surgery for upper tract stones.	Panel consensus, based on members' clinical training, experience, knowledge, and judgment for which there is no evidence.	Expert opinion
In pediatric patients with asymptomatic and nonobstructing renal stones, clinicians may utilize active surveillance with periodic ultrasonography.	Panel consensus, based on members' clinical training, experience, knowledge, and judgment for which there is no evidence.	Expert opinion

Goals of Therapy

The goals of surgical intervention for nephrolithiasis are the same for children as they are for adults: to achieve stone clearance with the minimal number of procedures, risk conferred, and complications. **The choice of intervention is determined primarily by the size and location of the stone, patient anatomy, and patient (and provider) preference.** Secondary considerations include patient comorbidities, composition of stone (if known), and equipment availability. Currently, the choice of the type of surgical intervention is heavily influenced by the site where the child obtains care (Wang et al., 2012).

Stone Clearance Definition

Stone clearance is generally considered the most important clinical outcome of surgery. Although children may have a greater capacity to clear residual fragments than adults (Gofrit et al., 2001), the presence of residual fragments has been associated with adverse clinical outcomes, including residual fragment growth or clinical symptoms. There is currently no consensus regarding the maximum size of residual fragments that are considered clinically significant for children, and as a result there is no clear definition as to what constitutes “stone-free” status. In addition, the method of assessing stone clearance varies by study and ranges from visual inspection at the time of URS to postoperative ultrasound or CT. It is thus difficult to directly compare the results and complications associated with different techniques, stone sizes, stone locations, and methods of outcome ascertainment.

Radiation

Patients with nephrolithiasis are exposed to radiation during diagnostic evaluation, operative treatment, and for surveillance after surgery (Routh et al., 2010a, 2010b; National Research Council, 2006; Kokorowski et al., 2012). URS and PCNL both typically use fluoroscopy, which delivers ionizing radiation, as does SWL unless ultrasound is used to target the stone. One single-institution study reported the median fluoroscopy times for unilateral URS, bilateral URS, and PCNL were 1.6 minutes, 2.5 minutes, and 11.7 minutes, respectively (Ristau et al., 2015). This was equivalent to 3 mSv for URS and 16.8 mSv for PCNL. Each patient received a median of one (IQR 1 to 3) CT scan and three (IQR 1 to 8) abdominal radiographs for the associated stone episode. The average cumulative radiation exposure for a patient who underwent a CT scan, PCNL, and three radiographs in a 1-year period was 32 mSv. Current guidelines recommend a maximum dose of 50 mSv in a 12-month period, and an average of <20 mSv/year over a 5-year period (Wrixon, 2008). Thus a therapeutic plan for a single large stone requiring PCNL may approach the limits of recommended ionizing radiation exposure.

Cumulative radiation exposure is a particularly important consideration for children with nephrolithiasis given they are more likely than adults to require future diagnostic imaging and surgical interventions that use ionizing radiation

(Katz et al., 2006; Kuhns et al., 2011). Additionally, the cumulative risk for radiation exposure may be higher in children than in adults because of a longer life expectancy and greater sensitivity of developing tissues to the effects of radiation.

Nelson et al. demonstrated substantial radiation exposure for children undergoing URS. Fluoroscopy time was the most important determinant of radiation exposure. However, other modifiable factors such as source-to-skin distance and fluoroscopy settings could be adjusted to decrease delivered radiation (Kokorowski et al., 2012). Consistent with the radiation safety concept that As Low As Reasonably Achievable (ALARA) emphasizes, recent techniques that utilize ultrasound for URS (Deters et al., 2014) and PCNL decrease radiation exposure in children. Checklists designed to reduce radiation exposure may also reduce fluoroscopy time, improve skin-to-image intensifier distance, and increase utilization of appropriate dose settings for children undergoing URS (Kokorowski et al., 2013). At our institution, ultrasound is used to obtain PNCL access. We also use intermittent, low-dose rather than continuous fluoroscopy when fluoroscopy is needed for URS and PCNL. Fluoroscopy technicians also operate the C-arm and reduce kVp, use pulse dosing, maximize skin-to-source distance, and narrow the image window to minimize radiation exposure while maintaining image integrity. We avoid routine magnification and, for smaller children, use pulse settings.

Ancillary Procedures/Anesthesia

Children requiring surgery to remove stones often need multiple anesthetics to complete the operative plan. For URS, the smaller size of children's ureters often precludes direct access with a ureteroscope. Because of the risk of ureteral perforation and stricture associated with active dilation in children, a ureteral stent may need to be placed if the ureteroscope cannot be introduced to allow for passive dilation of the ureter (Raza et al., 2005a; Minevich et al., 2005). However, a “pre-stent” increases the number of anesthetics needed to remove the stone. Similarly, SWL often requires retreatment to clear the stone. The need for multiple anesthetics is a concern considering the potential risk for neurotoxicity in the developing brain. Future comparative and cost-effectiveness studies should examine the disadvantages and potential harms of surgical interventions along with the efficacy. Such studies will be critical for shared decision making and understanding the impact of alternative interventions on outcomes that are important to patients and their families.

Surgical Antimicrobial Prophylaxis

Consistent with the 2008 AUA best practice statement on antibiotic prophylaxis and the 2014 AUA practice guide, prophylaxis is indicated in all patients undergoing URS or PCNL and is indicated for patients undergoing SWL who are at increased risk for infection (Wolf et al., 2008). There are no pediatric-specific recommendations. A urine culture should be obtained before all upper tract procedures to determine if the urine is sterile, and culture results are used to guide preoperative antibiotic therapy, particularly for patients undergoing percutaneous procedures, patients with high-grade obstruction, or patients with an indwelling stent (Wu and Docimo, 2004). In our practice, children with a negative urine culture undergoing uncomplicated SWL and ureteroscopy procedures receive perioperative cefazolin, and all children undergoing a percutaneous procedure or who have a preexisting ureteral stent or nephrostomy tube receive a fluoroquinolone or ampicillin/gentamicin. Antibiotics should not be continued for greater than 24 hours postoperatively unless there is a clinical concern for infection.

Ureteroscopic Management of Upper Urinary Tract Calculi

Historically, URS was used for stones below the iliac crest and for upper tract calculi after SWL failure (Wu and Docimo, 2004). URS was not considered primary therapy for upper tract stones in children because of complications from ureteral ischemia, perforation, stricture, and potential for development of vesicoureteral reflux as a result of dilation of small-caliber ureteric orifices. However, the indications for primary ureteroscopic management of upper tract calculi in children have significantly expanded because of continued miniaturization and availability of endourologic instrumentation and training of pediatric urologists in endourology. Stone clearance exceeding 85% with complications similar to the adult population have been reported for ureteroscopic management of renal calculi (Table 43.4). A recent systemic review reported the results of 14 studies of children 4 months to 18 years of age who underwent more than 1700 ureteroscopic stone removals (Ishii et al., 2015). The average stone clearance was 87.5%, and 10% of patients experienced complications less than or equal to Clavien 3. In another recent systematic review, overall stone clearance for URS was 85.5%, and complications occurred in 12% of patients. See Table 43.4 for outcomes of URS reported for pediatric patients.

TABLE 43.4

Historic and Contemporary Outcomes of Ureteroscopy for Pediatric Patients

AUTHOR	PATIENTS	PROCEDURES/PATIENT	MEAN AGE IN YEARS, (RANGE), (RANGE)	MEAN STONE SIZE, IN MM (RANGE)	STON LOCA

Kocaoglu and Ozkan, 2014	36	1	5.3 (1–13)	8.4 (4–18)	Uretera
Chedgy et al., 2015	21	1.5	8.6 (1.4–16)	9.6 (5–20)	Kidney uretera
Featherstone et al., 2017	18	1.8	10.4 (3.6–15)	13.3 (10–25)	Kidney uretera

NR, Not recorded.

There is weak evidence that location may modify the efficacy of URS. Cannon et al. (2007) reported a 76% stone clearance in 21 children with lower pole calculi and a mean stone diameter of 12 mm. Similarly, age may also be a determinant of URS outcomes. Children younger than 6 years of age were reported to have lower treatment success and higher complications (24.0% vs. 7.1%). Among children weighing less than 20 kg, Berrettini et al. (2018) reported that 37% of patients undergoing URS had complications, with a greater risk observed for younger and smaller children.

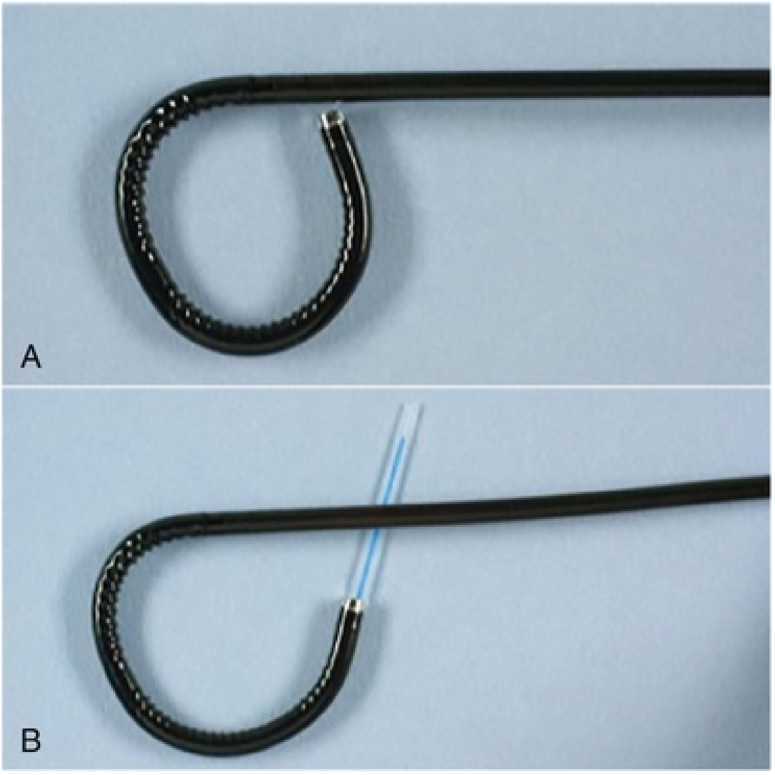
Even with modern ureteroscopes, pediatric ureters may require a period of stenting before definitive treatment because of the risk for ureteral perforation and stricture associated with active ureteral dilation or forcing a ureteroscope into a ureter that does not accommodate it (Long and Srinivasan, 2015; Dogan et al., 2011). These risks may be greater when a ureteral access sheath is used in younger children (Berrettini et al., 2017). **Approximately 25% of children undergoing URS required staged procedures** (Corcoran et al., 2007)**. However, the AUA and Endourological Society Guidelines do not recommend routine "presenting" before URS** (Assimos et al., 2016a).

There are only a limited number of studies directly comparing URS with SWL in children to help guide evidence-based practice. A recent retrospective, single-institution cohort study comparing URS to SWL reported that URS was associated with a 3.7 times greater odds of stone clearance after a single treatment among children with kidney stones (Freton et al., 2017). Mokhless et al. (2014) in Egypt performed a prospective, randomized trial of URS versus SWL in preschool children and reported similar stone clearance, complications, and operative times. The AUA/Endourological Society Guidelines also reported results of an unpublished meta-analysis that found similar stone clearance between SWL and URS in pediatric patients (Assimos et al., 2016a). These limited results are the basis for the recommendation in the 2016 AUA and Endourological Society Guidelines that **either SWL or URS should be first-line treatment for children with ureteral stones who have failed observation/MET or renal stone burden of ≤20 mm**.

Despite the increased utilization of URS for pediatric patients with ureteral and kidney stones, the optimal technique has not yet been defined. Laser dusting (high frequency of >50 Hz, low energy of <0.4 J) creates small <1-mm particles to enable spontaneous passage of the dust. In the fragmentation and extraction technique (low frequency, high energy), stones are fragmented into 1- to 4-mm pieces that are extracted from the kidney. The questions that emerge from dusting versus fragmentation are related to stone clearance and the patient experience. Preliminary reports from ongoing multicenter studies of adults have demonstrated that dusting is associated with lower stone clearance, but lower ureteral stent use, and similar unplanned health care encounters (Chew et al., 2016; Humphreys et al., 2018).

Equipment

A state-of-the art endourology suite that is familiar to the operative staff is important to effective and safe surgical treatment of the child with urinary stones. This setup includes semirigid and flexible ureteroscopes. In general, semirigid ureteroscopes usually have a 2.4-Fr to 3.5-Fr working port, and flexible ureteroscopes have a 1.8-Fr to 3.6-Fr working port. With flexible ureteroscopes, distal tip deflection up to 270 degrees facilitates access to most lower pole stones (Fig. 43.5). **However, smaller working areas and larger laser fibers may limit deflection, particularly for smaller children in which intrarenal angles are narrow and the collecting system is small (see Fig. 43.5C).**



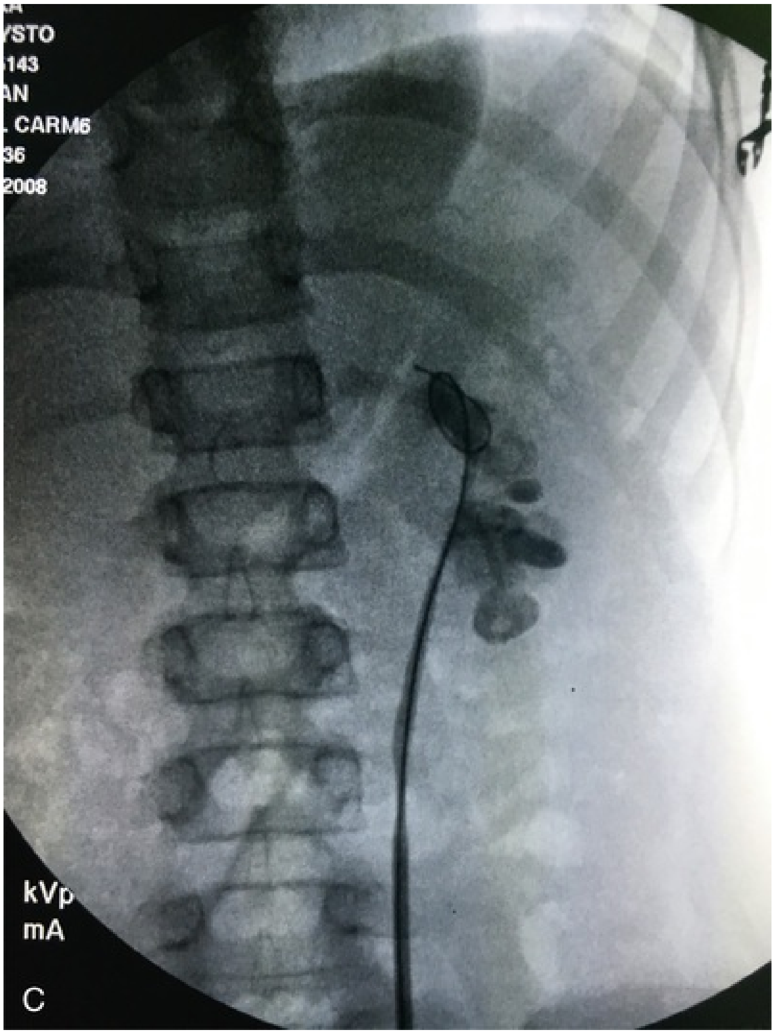


FIG. 43.5 Flexible ureteroscopes have 270-degree deflection of the distal tip (A), although tip deflection is compromised by passage of laser fibers (B), which may make accessing lower pole calyxes with sharp angles difficult (C).

The contents of a basic endourology suite are as follows:

- Ureteroscopes:
  - 7.5- to 8-Fr flexible ureteroscope
  - 4.5-Fr and 6.5-Fr semirigid ureteroscope
- Endourologic equipment:
  - Guidewires (minimum):
    - 0.035-inch guide wire with floppy hydrophilic tip (straight and angled)
    - 0.018- to 0.025-inch Glidewire (straight and angled)
  - Open-ended ureteral catheters (3-Fr, 4-Fr, and 5-Fr)

Dual-lumen catheter
Holmium laser
Basket devices: Zero-tip 4-wire, 16-wire
8- to 10-Fr coaxial ureteral dilators
Ureteral access sheaths (9.5-Fr and 12-Fr internal diameter)
Ureteral stents: 3.7-Fr, 4.6 to 4.7-Fr, 6-Fr, and 8-Fr

Ureteroscopic Technique in Children

All ureteroscopic procedures are performed under general anesthesia. A sterile urine culture should be confirmed before surgery. Children undergoing URS are placed in lithotomy position, similar to adults, using the appropriate size stirrups to avoid pressure wounds and nerve injuries. For infants, gel rolls underneath the knees can be used to provide a modified lithotomy position. Care is taken to ensure all pressure points are padded and the weight of the legs rests on the heels and not the calves or the knees where peroneal nerve injuries may occur. Following broad-spectrum antibiotic prophylaxis, rigid cystoscopy (7.5 Fr, 10 Fr, or 14 Fr) is performed to obtain a retrograde pyelogram and place a wire under fluoroscopic guidance. Initial ureteric orifice calibration is performed, and a safety wire is placed under C-arm fluoroscopic guidance with a 8- to 10-Fr dual-lumen catheter in ureters that have not been stented previously or when the rigid/flexible ureteroscope cannot be advanced easily. We do not use balloon dilation of the ureteric orifice because of concern for development of ureteral stricture from ischemia. If we encounter difficulty passing the 8- to 10-Fr dilator easily, we place a 4.6- or 4.7-Fr ureteral stent to passively dilate the ureter for at least 10 days before returning for the formal URS. We recommend against active dilation of the distal ureter because of the risk for ureteral injury and because the diameter of the ureter proximal to the ureteral orifice also limits safe ureteroscopy, particularly if an access sheath is used.

The decision to use a flexible or semirigid ureteroscope is determined primarily based on location of the stone and anatomic factors. Semirigid ureteroscopy for ureteral calculi and flexible ureteroscopy for proximal ureteral or renal calculi are routinely performed with a safety wire in place. Ureteral access sheaths (10 to 12-Fr or 12 to 14-Fr) are routinely used to facilitate flexible URS, especially in cases of large proximal ureteral stones and larger renal stone burdens when basketing is required. Initially described in eight children, ureteral access sheaths have been reported to facilitate repetitive upper tract access, reduce intrarenal pressures, decrease operative time, and improve stone clearance in adults (Singh et al., 2006). **Access sheaths also may facilitate flexible ureteroscopy when altered anatomy or tortuous ureters are encountered.**

Although the efficacy of URS is less dependent on stone position than SWL, consideration must be given to the smaller size of children's kidneys when operating for a lower pole stone. Smaller kidneys have less room to maneuver a ureteroscope and have sharper angles, which may make accessing stones in the lower pole difficult (see Fig. 43.5C). Given these technical considerations, we use a 150-µm Holmium laser fiber to access stones in the lower pole, which improves deflection compared with larger fibers (Kuo et al., 1998). We routinely use a 200-µm fiber for ureteral stones and stones located in the mid and upper pole calyces.

Irrigating fluid should be isotonic and body temperature to avoid hyponatremia and hypothermia. Calculi are basket-extracted when feasible or fragmented using a holmium : YAG laser to facilitate removal. **The decision to place a ureteral stent postoperatively is based on the duration of the procedure, the number of passes with the ureteroscope, and the degree of visible ureteral trauma or edema at the conclusion of the procedure.** Although the tendency in some series was to leave a stent in place after URS in most children, several authors reported no short- or long-term sequelae despite leaving a postoperative stent in less than 20% of cases (Herndon et al., 2006). In our experience, the decision to place a stent after ureteroscopy is made on an individual patient basis and depends on surgeon experience and degree of visible ureteral trauma at the conclusion of the procedure. If the child can tolerate leaving a urethral string in place for 5 to 7 days, the patient's parents are asked to remove the stent at home; otherwise, the stent is removed under brief anesthesia after 7 days.

Limitations and Complications

The complications of URS include ureteral injury, urinary tract infection, and bleeding. Serious complications (greater than Clavien 3) are uncommon. These include unrecognized ureteral injury including mucosal flaps and tears, perforation, false passage, and partial to complete ureteral avulsion. Should a ureteral injury occur, the procedure should be aborted and a ureteral stent should be placed to mitigate shear force injury on the ureter, ischemic damage, and extravasation of irrigant or urine. Injury can occur during introduction of the ureteroscope or either antegrade or retrograde passage of instrumentation (guidewires, baskets, dilators), especially in the area of an impacted ureteral calculus. Attempting to withdraw a basket-entrapped calculus too large for the ureter to accommodate can result in any of the injuries discussed earlier.

If a ureteral stricture is encountered or develops after ureteroscopy, a retrograde pyelogram can show the degree, length, and location of narrowing. Short mid-ureteral strictures can undergo prolonged stent placement, although the long-term success of this is uncertain. Balloon dilation of ureteral strictures is not used by the authors, with laser incision being preferred. We recommend formal reconstruction, which can often be performed robotically, for longer, denser, or recurrent strictures. Distal strictures may be treated with a ureteroneocystostomy. Proximal or mid-ureteral strictures may necessitate pyeloplasty or excision and primary anastomosis, respectively.

Key Points: Ureteroscopic Management of Upper Tract Calculi

- Miniaturization of endoscopic instruments with modification of techniques used for adults has allowed children with calculi less than 15 mm to be treated effectively and safely.
- Routine prestenting before URS is not recommended.
- Postoperative stenting is based on the duration of the procedure, number of passes with the ureteroscope, and degree of visible ureteral trauma or edema at the conclusion of the procedure.
- The most common complications involve unrecognized ureteral injury, including mucosal flaps and tears, perforation, false passage, and partial to complete avulsion.

Shock Wave Lithotripsy

The introduction of SWL during the early 1980s revolutionized minimally invasive treatment of urolithiasis. Since the initial report on successful SWL use in children in 1986 (Newman et al., 1986), large series have reported complication, safety, and stone clearance comparable to adult cohorts (Myers et al., 1995; Muslumanoglu et al., 2003; Raza et al 2005b; Rizvi et al., 2003; Aksoy et al., 2004; Demirkesen et al., 2006; Elsobky et al., 2000). SWL may be more effective in children than in adults, possibly caused by smaller body size and shorter skin-to-stone difference (Kurien et al., 2009). However, SWL outcomes are difficult to interpret from the existing literature because of variation in the type of lithotripter, number of shocks administered, and retreatment rates.

Along with URS, SWL is a treatment option for upper tract calculi 15 mm or smaller in children (Assimos et al., 2016a)**. When used as a primary treatment option for upper tract calculi, SWL efficacy ranges from 68% to 84%** (Myers et al., 1995; Rizvi et al., 2003; Defoor et al., 2005). In a series of 216 children (mean age of 6.6 years) with a mean stone size of 15 mm undergoing SWL with the Dornier HM3 lithotripter, Landau reported stone clearance of 80% at 3 months. However, stone clearance in children with a history of a urologic anomaly or urinary tract reconstruction is low (Landau et al., 2009). Depending on body habitus, stone size, and stone location, URS or PCNL may be better treatment options for these children (Nelson et al., 2008).

Stone size is an important determinant of stone clearance after SWL. Ather and Noor examined whether size modified the efficacy of SWL efficacy among 105 children younger than 14 years of age. They reported overall stone clearance of 95% after a mean of 1.7 SWL treatments (Ather and Noor, 2003). Demonstrating the importance of stone size in determining efficacy of SWL, Elsobky et al. (2000) reported a 91% stone clearance for mean stone diameter less than 10 mm versus 75% stone clearance for stone size greater than 10 mm. Although it is possible to treat very large stone burdens with SWL, concerns include the need for more shocks delivered, frequent retreatment sessions, and increased risk for postoperative obstruction. Further study delineating a clear size cutoff for uncomplicated upper tract stone burden is required to counsel parents regarding the most effective first-line therapy for renal calculi between 10 and 15 mm.

Although SWL is considered a treatment option for pediatric patients

with renal stones greater than 20 mm, the probability of clearance is lower than PCNL and requires multiple treatments (Al-Busaidy et al., 2003; Lottmann et al., 2001). For pediatric patients who undergo SWL for stones greater than 20 mm, the AUA and Endourological Society Guidelines recommend placing a ureteral stent to decrease the risk for major complications (Assimos et al., 2016a, 2016b). Because of the abundance of studies that have demonstrated poor efficacy of SWL for large renal stone burdens in adults and the safety and high efficacy of PCNL in this clinical setting, it is the authors' practice not to perform SWL for stones greater than 15 mm in pediatric patients.

Stone location is also an important determinant of SWL outcomes; however, the most effective management of lower pole calculi has yet to be determined in children, and there are no location-specific guidelines for pediatric patients. Stone clearance for lower pole stones in small retrospective series range from 56% to 61% with retreatment rates of 40% (Onal et al., 2004; Özgür Tan et al., 2003). A recent systematic review and meta-analysis comparing SWL, URS, and PCNL in adults for lower pole stones less than 2 cm favored PCNL over SWL and URS over SWL, particularly in stones 10 to 20 mm (Donaldson et al., 2015). Whether these results in adults are generalizable to children is uncertain.

SWL failure and retreatment rates were associated with increased mean stone burden, increased infundibular length, and infundibulopelvic angle greater than 45 degrees (Onal et al., 2004; Özgür Tan et al., 2003). Although CT is not necessary before SWL or in the management of most pediatric stone disease, stone attenuation on CT has been associated with stone fragmentation. Stone attenuation less than 1000 HU was associated with treatment success in children (El-Assmy et al., 2013; McAdams et al., 2010).

Stone composition is also an important effect modifier of SWL efficacy. Cystine stones are uniquely challenging because of their hardness and high recurrence rates. In a small series, Slavkovic reported stone clearance of 50% in six children with cystine stone burden ranging from 2 to 25 mm (Slavkovic et al., 2002). Other authors have proposed that cystine stones formed within 2 years of therapy may be more easily fragmented with SWL and that stone number may be more closely associated with stone clearance than stone diameter.

Shock Wave Lithotripsy Technique in Children

SWL is typically performed under general anesthesia, although intravenous sedation has been successfully employed in some older children (Aldridge et al., 2006). Bowel preparation is seldom used to avoid dehydration and electrolyte imbalance postoperatively. Ureteral catheters with retrograde opacification are occasionally employed by some clinicians to aid in the localization of radiolucent calculi. **Increased shock frequency and energy level have been associated with lower stone clearance among adults** (Ozkan et al., 2015)**, but the optimal settings for children are unknown.** A retrospective cohort study of children treated with SWL in Turkey reported similar stone clearance and complications for shock frequencies of 60 and 90 shocks per minute (Kaygisiz et al., 2018).

The 2016 AUA and Endourological Society Guidelines recommended placement of a ureteral stent or nephrostomy for SWL for stones greater than 20 mm. Although indications for stent placement before SWL are poorly defined, **additional relative indications include solitary kidneys, obstruction, or abnormal anatomy.**

Limitations and Concerns

The short-term effects of SWL, which are usually self-limiting, include hematuria (up 44%) and subcapsular or perirenal hematoma (Yucel et al., 2012). In addition, children treated with SWL need to pass stone fragments and are at risk for intermittent renal colic, emergency department visits for pain control, and steinstrasse. Difficulty with focusing SWL can lead to injury to adjacent structures including the colon, vasculature, lung, spleen, and pancreas (Yucel et al., 2012).

In addition, as noted earlier, stone clearance after single SWL treatment is low. As a result, children are subjected to multiple treatments requiring general anesthesia (Aldridge et al., 2006). The need for multiple treatment sessions is concerning because the effects of shock waves on renal tissue are unclear. A growing body of evidence in adults indicates that shock waves result in renal vessel vasoconstriction and that renal tubular injury and subcapsular hematoma from cavitation and shear forces are dependent on the kilovoltage applied (Lingeman et al., 2003). In a large series of 340 adult patients with a mean follow-up period of 19 years after SWL, Krambeck et al. reported an increased risk for hypertension and diabetes mellitus related to bilateral treatment, number of administered shocks, and treatment intensity (Krambeck et al., 2008). **Despite some studies showing no long-term effects of SWL, a recent population-based cohort study of adults also demonstrated that SWL was associated**

with 40% increased risk for incident hypertension (Denburg et al., 2016; Yucel et al., 2012; Griffin et al 2010; Akin and Yucel, 2014; Fayad et al., 2010). It is our practice to discuss with patients and caregivers the potential risk for hypertension associated with SWL during the shared decision-making process considering the possibility that children's kidneys may be more vulnerable to injury, the independent association between kidney stone disease and hypertension, and the longer lifespan over which hypertension may develop following surgical treatment. Long-term prospective data in children are needed.

Key Points: Conservative Management and Shock Wave Lithotripsy

- Smaller and more distal stones have a higher probability of spontaneous passage.
- α-Blockers may increase spontaneous passage of ureteral stones in pediatric patients.
- Although the overall stone clearance of SWL approaches that of URS for stones less than 15 mm, there is a greater need for retreatment.
- SWL has been associated with an increased risk for hypertension.

Percutaneous Nephrolithotomy

The safety and efficacy of PNCL for large stone burdens have been well established in adults. Urologists initially were reluctant to perform PCNL in children because of concerns regarding the use of large instruments in pediatric kidneys and parenchymal damage and the associated effects on renal function, radiation exposure, and the risk for major complications including sepsis and bleeding. However, with significantly accumulated experience, **PCNL is considered first-line therapy for renal stones greater than 20 mm in children, with stone clearances of approximately 90%** (Assimos et al., 2016b). PCNL has replaced open surgery as the treatment of choice for large stone burdens in all children (Table 43.5).

NR, Not recorded.

The earliest pediatric PCNL series were performed using standard adult-sized instruments. Woodside et al. (1985) first reported a series of seven patients (age range 5 to 18 years) who were rendered stone-free without complications using adult percutaneous techniques and equipment. Mor et al. (1997) subsequently reported another pediatric PCNL series using adult-sized instruments. These early series avoided performing PCNL in small children (younger than 5 years of age) because of concerns of parenchymal damage.

PCNL for pediatric patients using an access tract of up to 30 Fr and adult-sized instruments reported high stone clearance (Bilen et al., 2007; Salah et al., 2004; Samad et al., 2006; Zeren et al., 2002). However, Desai et al. (2004) demonstrated that the risk for bleeding increases with access tract size. This risk may be higher in children because the relative size of a 24- to 30-Fr access tract to children's smaller kidneys has been estimated to be 72 Fr (Jackman et al., 1998). The continued miniaturization of access sheaths and nephroscopes and improvements in stone fragmentation technology have allowed use of smaller access tracts, which mitigates the risk for bleeding while maintaining stone-free rates at or above 75%. Mini- and micro-PCNL have become increasingly common for large renal stones for both children and adults. Mini-PCNL usually refers to access tracts of less than 20 to 24 Fr, whereas micro-PCNL refers to tracts less than 10 Fr. The comparative effectiveness of and indications for newer techniques such as mini-PCNL, ultra-mini-PCNL, and micro-PCNL among pediatric patients is an active area of investigation (Dede et al., 2015). With continued improvement in technology and technique, the indications for PCNL in children are expected to continue to increase.

Despite the AUA guidelines that state both SWL and PCNL are options for children with renal stones greater than 20 mm, we recommend PCNL for these patients because SWL is less effective than PCNL for large renal stones. In addition, it is possible that the recently reported association between SWL to the kidney and hypertension (Denburg et al., 2016) may be greater among children because of the larger area of the kidney affected by the shock waves and the longer lifespan over which hypertension may develop. However, PCNL and percutaneous renal access in children should be performed only by experienced urologists who have the necessary training and equipment.

Percutaneous Nephrolithotomy Planning for Pediatric Patients

PCNL is technically challenging, and surgeon experience with PCNL is paramount in developing treatment plans to optimize efficacy with minimal morbidity. The AUA and Endourological Society Guidelines recommend CT before PCNL (Assimos et al., 2016b). Films must be reviewed carefully to determine if stones are amenable to a percutaneous procedure and to determine the optimal calyx to access the stone. Stone size, stone location, and adjacent organs should be considered. In addition, any alteration in renal anatomy caused by scoliosis, lordosis, or kyphosis should be considered. **The risks associated with PCNL must be reviewed with the consenting parent or guardian, including bleeding requiring transfusion, delayed renal hemorrhage requiring angioembolization, sepsis, pneumothorax, hemothorax, urothorax, incomplete stone clearance, and injuries to adjacent organs.**

Urinary tract infections should be treated before PCNL. A urine culture and antibiotic sensitivities should be checked 2 to 3 weeks before the procedure. A positive culture requires a full course of antibiotics. However, it should be noted that bladder cultures may not reflect stone cultures or urine cultures obtained from the renal pelvis. Empiric treatment with ciprofloxacin among adults 1 week before PCNL may reduce infectious complications (Mariappan et al., 2006). Broad-spectrum intravenous antibiotics (e.g., ampicillin and gentamicin) should be given at the time of the procedure.

Percutaneous Nephrolithotomy Technique for Pediatric Patients

PCNL is performed under general anesthesia. A warm operating room, warmed isotonic irrigation solution, shorter operative times, proper draping, and monitoring of body temperature should decrease the incidence of hypothermia. We first perform cystoscopy and place a 4- or 5-Fr open-ended ureteral catheter just below the ureteropelvic junction, which can be used for retrograde pyelograms or instillation of saline to distend the collecting system. We then position the patient prone over gel bolsters and obtain renal access with ultrasound, although fluoroscopy is commonly used (Figs. 43.6 and 43.7). Assessing the degree of mobility in the trunk and extremities is important for positioning patients for PCNL. Patients must be placed in the most comfortable position possible without excessive contortion or flexion of the joints. Special attention must be paid to latex precautions in patients with myelomeningocele, and, in all cases, proper padding of pressure points is mandatory.

FIG. 43.6 (A–C) Lower pole access for mini-percutaneous nephrolithotomy obtained using ultrasound. The needle appears as a linear echogenic focus on the right side of the image.

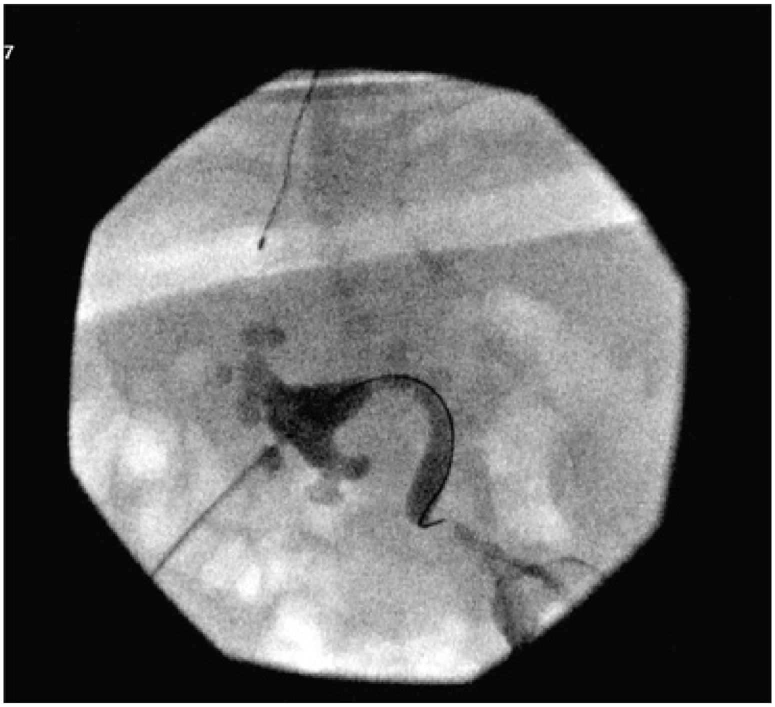

FIG. 43.7 Mid-pole access for mini-percutaneous nephrolithotomy for a pelvis stone in an infant.

After selection of the desired calyx, a 16- or 18-gauge spinal needle is placed with the assistance of fluoroscopy or ultrasound. The authors obtain access with ultrasound using the technique described by Chu et al. (2016). For lower pole access, the posterior calyx is identified, which, in >90% of patients, is the calyx immediately superior to the most inferior calyx on anteroposterior fluoroscopy (Miller et al., 2013). Upper pole is obtained below the 11th rib and in the medial calyx to decrease the risk for pneumothorax. If CT guidance is required for renal access in a child with spinal dysraphism or an aberrantly positioned kidney, Interventional Radiology obtains renal access.

A small skin incision is made with a No. 11 scalpel, and 8-Fr and 10-Fr coaxial dilators are passed over the guidewire into the collecting system. A safety wire introducer or dual-lumen catheter is used to place a safety wire. After placement of two wires (with the safety wire preferentially down the ureter), we use an 18-Fr balloon dilator and PTFE sheath for renal access. **Children's kidneys, and especially infant's kidneys, are more mobile than adult kidneys and often push away when obtaining initial needle access and placing the access sheath.** Attention to the location of the tip of the balloon in the collecting system and bony landmarks is critical when advancing the sheath under fluoroscopy. A retrograde pyelogram is performed using the ureteral catheter to redefine the collecting system anatomy. Before placing a sheath in small children, we trim it to shorten the extracorporal component, which we find improves maneuverability and limits torque on the kidney. After obtaining access, we use a 15- to 18-Fr rigid nephroscope, and our preference is a lithotripter, which uses both ultrasonic and mechanical energy to fragment and remove the stone(s). We use the Olympus ShockPulse lithotripter because it combines the greater efficacy of the ACMI/Olympus Cyberwand (compared with Holmium laser) with probes that are small enough (2.1 to 11.3 Fr) to be used in mini-nephroscopes and semirigid ureteroscopes. Because of the sharper angles and narrower infundibula of children's kidneys, we use a flexible pediatric cystoscope and/or flexible ureteroscope to confirm stone clearance and access mid-pole calyces for residual fragments. Following stone clearance, we routinely place a nephrostomy tube, the size of which depends on the child's age. The authors use a 10- to 12-Fr Malecot in infants and a 14-Fr Malecot in adolescents, or an 8.5-Fr Cope loop nephrostomy tube. If there is substantial stone burden and/or substantial edema at the UPJ, we place a ureteral stent in addition to the nephrostomy tube. In this setting, the nephrostomy tube is removed after the urine clears and the patient is safe for discharge, usually on postoperative day 1. At this time, there is insufficient evidence that tubeless PCNL is a safe option for children.

Historically, primary PCNL with adjunctive SWL to clear residual fragments was often performed for children (“sandwich therapy”; Samad et al., 2006; Mahmud and Zaidi, 2004). However, with efficacy of PCNL around 90% for large stone burdens, miniaturization of nephroscopes, and the concerns of hypertension for SWL, the indications for sandwich therapy are limited.

Percutaneous Nephrolithotomy Complications

The proportion of children who experience some complication after PCNL ranges from 15% to 39%. Although most of these complications are minor, complications greater than or equal to Clavien 3 occur in 1% to 16% (see Table 43.5). The probability of operative blood loss requiring transfusion is consistently <10%. Complications included postoperative fever (30%) and need for transfusion (24%). **Transfusion was associated with operative time, sheath size, and stone burden** (Zeren et al., 2002). In 135 children with a mean age of 8.9 years and a mean stone burden of 507 mm^2, Salah et al. (2004) reported a 98.5% stone-free rate using ultrasonography through a 26-Fr nephroscope.

Complications were low (8% urine leak rate and 0.7% transfusion rate), with only one patient requiring a second procedure. When stratified by tract size (14 Fr, 20 Fr, and 24 Fr), efficacy rates were similar in all groups, but there were no complications or transfusions in the 14-Fr tract group (Bilen et al., 2007). A large multicenter study demonstrated that the most significant determinants affecting complication rates were operative time, sheath size, mid-calyceal puncture, and partial staghorn formation (Onal et al., 2014). PCNL has not been shown to cause loss of kidney function or scarring (Mor et al., 1997).

Should significant bleeding occur, the operation should be aborted and either a Foley catheter or re-entry catheter should be placed in the collecting system through the nephrostomy tract, and treated as clinically indicated for adult patients. Should a renal pelvis injury occur, the operation should be stopped and an antegrade ureteral stent should be placed, if feasible. **Treatment of known complications of PCNL in children, including hydrothorax, colonic injury, and postoperative bleeding, is similar to adults**. Because of the possibility of bleeding requiring embolization or hydrothorax requiring a chest tube, we recommend that PCNL only be performed at children's hospitals with a pediatric interventional radiology team capable of performing these procedures.

Key Points: Percutaneous Nephrolithotomy

- PCNL is indicated for treatment of a large upper tract stone burden (>20 mm) in children.
- Fluoroscopy or ultrasound can be used to obtain access for PCNL.
- Despite efficacy rates approaching 90%, PCNL is associated with risks including bleeding, delayed renal hemorrhage, sepsis, pneumothorax, hemothorax, urothorax, incomplete stone treatment, and injuries to organs adjacent to each respective kidney.

Laparoscopic and Robotic-Assisted Pyelolithotomy

Consistent with the recommendations in the 2016 AUA and Endourological Society recommendations against routine open, laparoscopic, and robotic surgery for pediatric kidney stones, laparoscopy and robotic-assisted surgery is not indicated for upper tract stones in pediatric patients with normal urinary tract anatomy (Assimos et al., 2016b). The rationale for this recommendation is that URS, SWL, and PCNL have high rates of success and lower risks for serious complications. The primary exception to this is in children or adolescents with renal or ureteral stones and a coexisting anatomic anomaly, such as UPJ obstruction. In these patients, robotic (or laparoscopic) pyeloplasty with concomitant stone removal is indicated (Lee et al., 2007).

Secondary Prevention

Fluid

Fluid intake is a critical component of stone prevention by effectively reducing the concentration of lithogenic factors including calcium, oxalate, uric acid, and cystine. Although it has been clearly shown that high daily fluid intake reduces the risk for recurrent stone formation (Borghi et al., 1996), the exact prescription is unknown. Most clinicians recommend intake at least equal to calculated maintenance rates in children and greater than 2 to 2.5 L in adolescents and adults. Even higher fluid intake levels (1.5 to 2 L/m^2) may be recommended for children with cystinuria or primary hyperoxaluria. Increased intake requirements may be required during periods of increased insensible water loss. As to fluids other than water, reports suggest that fluids that increase urinary pH and citrate excretion such as orange juice, lemonade, and black currant juice, as well as those that increase urinary volume such as coffee, tea, beer, and wine, reduce the risk for calcium stone formation. Conversely, grapefruit juice appears to increase the risk for calcium-based stones. Whether or not soft drinks increase lithogenic potential remains controversial (Borghi et al., 2006; Taylor and Curhan, 2006).

Sodium

There is an association between increased sodium intake, urinary calcium excretion, and calcium stone formation (Taylor and Curhan, 2006). Increased sodium intake promotes calciuria by competing for reabsorption at the level of the renal tubules. A low-salt diet corresponding to less than 2 to 3 mEq/kg/day in children or less than 2.4 g/day in adolescents or adults is generally recommended for patients with hypercalciuria or calcium-containing stones. A low-salt diet may also reduce urinary cystine excretion in patients with cystinuria.

Calcium

Higher calcium intake was initially thought to increase the risk for stone formation; however, there now is substantial evidence that a higher calcium diet is associated with a reduced risk for stone formation (Curhan et al., 1997). A potential mechanism that might explain this paradox is that higher calcium intake effectively binds dietary oxalate in the gut, thereby reducing intestinal absorption and eventual urinary oxalate excretion. The current recommendation for stone formers is not to restrict dietary calcium intake, in part also because of the long-term risk for osteoporosis. Excess consumption of vitamin D with or without calcium supplements can also induce excessive urinary calcium excretion, although the association with stone formation is uncertain.

Animal Protein

There is evidence for a role of dietary animal proteins (meat, fish, and poultry) in calcium oxalate stone formation. The metabolism of sulfur-containing amino acids in animal meat generates an acid load in the form of sulfuric acid. As a result, excessive dietary animal protein intake causes increased urinary calcium excretion and reduced urinary citrate excretion and pH. Vegetable and dairy protein sources do not appear to carry the same lithogenic potential. Consumption of excessive amounts of dietary animal protein also results in increased purine load and increased uric acid production, and it may contribute to both uricosuria and more acidic urine. In cystinuric patients, there is little evidence to support the dietary restriction of proteins high in cystine content; however, reducing animal protein intake might be helpful by increasing urinary pH. **It is generally recommended that children with calculi should not eat excessive amounts of protein but should aim for 100% of the daily recommended allowance for age to supply adequate substrate for growth**

and nutrition.

Oxalate

The role of dietary oxalate in stone formation is controversial because only approximately 10% to 20% of urinary oxalate excretion is derived from the diet. As a precautionary measure, most clinicians recommend limiting dietary oxalate ingestion in calcium oxalate stone formers who demonstrate evidence of hyperoxaluria. High oxalate-containing foods include certain nuts (almonds, peanuts, cashews, walnuts, and pecans), spinach, soy beans, tofu, rhubarb, beets, sweet potatoes, wheat bran, okra, parsley, chives, black raspberries, star fruit, green tea, and chocolate. Vitamin C supplements have been associated with increased risk for calcium oxalate stone formation because, as mentioned earlier, oxalate is a by-product of ascorbic acid metabolism, therefore these supplements should be discontinued in calcium oxalate stone formers with hyperoxaluria (Taylor et al., 2004).

Citrate

Potassium-rich foods such as fruits and vegetables usually contain large amounts of citrate, which are protective against calcium oxalate stone formation. In many studies, a diet high in potassium is protective against urolithiasis (Curhan et al., 1997). In addition a potassium-deficient diet can cause increased urinary calcium excretion, overt hypokalemia, and hypocitraturia. One recent study suggests that chronically low potassium intake in the absence of overt hypokalemia may also result in low urinary potassium and citrate levels (Domrongkitchaiporn et al., 2006). As a result, a diet containing potassium-rich fruits and vegetables can theoretically increase urinary citrate excretion directly because of the citrate content found in these foods and indirectly through the dietary potassium content.

Others

Magnesium complexes with oxalate and may prevent enteric oxalate absorption and decrease calcium oxalate supersaturation in the urine. In some studies, higher dietary magnesium has been associated with a lower risk for stone formation in men (Taylor et al., 2004), and supplementation may be helpful in the treatment of children with secondary hyperoxaluria. Carbohydrate ingestion has been associated with hypercalciuria, and sucrose ingestion has been found to be associated with urolithiasis (Curhan et al., 1997). Phytate, a dietary factor found in many high-fiber foods (e.g., cereals, legumes, vegetables, nuts), appears to bind calcium avidly and may inhibit calcium oxalate stone formation.

Medications

Pharmacotherapy is warranted for children in whom fluid/dietary therapy is ineffective in controlling stone formation.

Diuretics

A thiazide diuretic is often required for children with hypercalciuria that does not respond to a restricted sodium diet. The usual recommendation is hydrochlorothiazide 1 to 2 mg/kg per day (adult 25 to 100 mg/day). Potassium citrate can be added to mitigate the effects of potassium depletion.

Alkali Agents

Treatment with either potassium citrate (2 to 4 mEq/kg/day, adults 30 to 90 mEq/day) (Barcelo et al., 1993) **or potassium-magnesium citrate** (Ettinger et al., 1997) **has been shown to reduce the recurrence of calcium oxalate stone formation in patients with low or normal citrate excretion.** Sodium citrate is generally considered less ideal as it is associated with increased sodium delivery to the nephron. Treatment is considered safe with only minor gastrointestinal side effects; however, one potential concern is that overtreatment with alkali may increase the risk for calcium phosphate stone formation by increasing the urinary pH >6.5, thereby decreasing the calcium phosphate supersaturation product. Potassium citrate is also used to alkalinize the urine in patients with uric acid lithiasis (goal of urine pH >6.5), cystinuria (goal of urine pH >7), and hyperoxaluria.

Thiol-Containing Agents

These agents are used exclusively for patients with cystinuria in whom fluid/dietary modifications and urinary alkalinization are ineffective in preventing stone recurrences. The two most common agents are D-penicillamine and α-mercaptopropionylglycine (tiopronin). Cystine is formed as a dimer of cysteine, and these agents work by reducing the disulfide bond that bridges two molecules of cysteine. The thiol group combines with cysteine to form a more soluble cysteine–drug product combination that can be excreted. Unfortunately, D-penicillamine has a large number of adverse side effects including febrile reactions, gastrointestinal discomfort, liver dysfunction, impaired taste, bone marrow suppression, trace metal deficiencies, membranous glomerulopathy, myasthenia gravis, and skin eruptions (elastosis perforans serpiginosa). The incidence of adverse effects for alpha-mercaptopropionylglycine is similar but may be slightly less. Monitoring of liver enzymes, complete blood count, urinalysis, and copper and zinc levels should be performed regularly. Special assays (solid-phase assay or high performance liquid chromatography) can readily distinguish between urinary cystine and cysteine–drug complexes and may help in guiding long-term medical therapy.

Allopurinol

The mainstay of therapy for most children with uric acid calculi is a combination of high urine flow rate and alkalinization of the urine. Allopurinol (4 to 10 mg/kg/day, adult maximum 300 mg/day) is indicated in patients with both hyperuricemia and hyperuricosuria such as PRPSS or HPRT deficiency. Inhibition of xanthine dehydrogenase by allopurinol may lead to accumulation and urinary excretion of xanthine. Rarely, a secondary xanthinuria with xanthine calculi is observed in children on chronic therapy. Allopurinol may also be the agent of choice for treating hyperuricosuric calcium oxalate urolithiasis if there is no concomitant evidence of hypercalciuria, hyperoxaluria, or hypocitraturia (van Woerden et al., 2004).

Pyridoxine

Pyridoxine is an important cofactor of the AGT enzyme. Approximately 10% to 30% of children with PH1 are pyridoxine sensitive (>30% reduction of urinary oxalate excretion). In particular, patients who are homozygous for *Gly170Arg* or *Phe152Ile* mutations are more likely to respond and have preserved renal function over time with adequate treatment (van Woerden et al., 2004). In patients with suspected PH1, treatment should be initiated (2 to 5 mg/kg/day) and titrated upward (8 to 10 mg/kg/day) until a diagnosis can be made and response assessed. Large doses of pyridoxine have been known to induce sensory neuropathies. There is currently no evidence to suggest that pyridoxine supplementation is beneficial in the treatment of other forms of hyperoxaluria unless a true pyridoxine deficiency exists.

SECTION E

Genitalia

OUTLINE

44 Management of Abnormalities of the External Genitalia in Boys

45 Hypospadias

46 Etiology, Diagnosis, and Management of the Undescended Testis

47 Management of Abnormalities of the Genitalia in Girls

48 Disorders of Sexual Development Etiology, Evaluation, and Medical Management

Management of Abnormalities of the External Genitalia in Boys

Lane S. Palmer MD, FACS, Jeffrey S. Palmer MD, FACS, FAAP

The normal anatomy of the penis includes the prepuce (foreskin), glans, urethral meatus, coronal sulcus, and penile shaft. The ventral surface of the penile skin has the median raphe that is contiguous with the scrotal raphe and ends at the edge of the outer prepuce. Anomalies of the penis and scrotum are common and may be congenital, acquired, or iatrogenic. **The congenital anomalies may result from a disorder of sexual differentiation, genital differentiation, or genital growth and may be associated with other syndromes** (eTable 44.1) or organ systems. For example, up to 50% of children with congenital anorectal malformations also have an associated urologic malformation.

eTABLE 44.1

Male Genital Anomalies That Commonly Occur in Various Syndromes (Microphallus, Hypospadias, Ambiguous Genitalia, and Bifid Scrotum)

ANOMALY	FEATURES
Anencephaly	
Aniridia–Wilms tumor association	WAGR syndrome: Wilms tumor, aniridia, genitourinary abnormalities or gonadoblastoma, and mental retardation
Bladder exstrophy	
Börjeson-Forssman-Lehmann syndrome	Microcephaly, mental retardation, large ears
Carpenter syndrome	Acrocephaly, polydactyly and syndactyly of feet, congenital heart disease
CHARGE association	Coloboma, heart malformation, atresia choanae, retarded growth and development, genital anomalies, ear anomalies and/or deafness
Cloacal syndrome	

Fraser syndrome	Cryptophthalmos, mental retardation, ear anomalies
Johanson-Blizzard syndrome	Hypoplastic alae nasi, hypothyroidism, mental retardation, pancreatic insufficiency, deafness
Meckel-Gruber syndrome	Occipital encephalomeningocele, micrognathia, polydactyly, cystic renal dysplasia
Noonan syndrome	Webbed neck, pectus excavatum, pulmonic stenosis, short stature
Opitz syndrome	Hypertelorism, hypospadias, mild-to-moderate mental retardation
Pallister-Hall syndrome	Hypothalamic hamartoblastoma, hypopituitarism, imperforate anus
Popliteal pterygium syndrome	Popliteal web, cleft palate, lower lip pits
Prader-Willi syndrome	Hypotonia, obesity, small hands and feet, mild to moderate mental retardation
Rapp-Hodgkin ectodermal dysplasia syndrome	Hypohidrosis, oral clefts, dysplastic nails
Rieger syndrome	Iris dysplasia, hypodontia
Robinow syndrome	“Fetal face syndrome”; flat facial profile, hypertelorism, short forearms, thoracic hemivertebrae
Schinzel-Giedion syndrome	Growth deficiency, mental retardation, widely patent fontanelles, short forearms and legs, renal anomalies
Smith-Lemli-Opitz syndrome	Ptosis of eyelids, syndactyly of second and third toes, microcephaly, failure to thrive with short stature, mental retardation
Triploidy syndrome	
Trisomy 4p, 9p, 18, 20p, 21, 22, 9p, 10q, 11p, or 15q deficiency

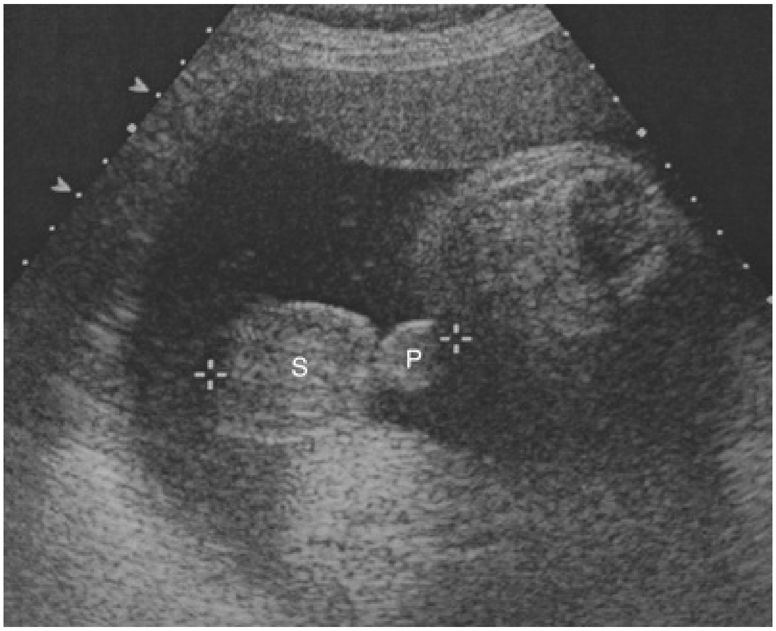
From Jones KL: *Smith's recognizable patterns of human malformation,* ed 5, Philadelphia, 1997, Saunders.

Although ultrasonographic technology has evolved in the past decade, permitting earlier fetal sex determination (Efrat et al., 2006), it is insufficiently accurate to recommend before 12 weeks of gestation (Odeh et al., 2009). However, ultrasonography after 13 weeks of gestation accurately assesses sex determination in 99% to 100% of cases without malformed external genitalia (Odeh et al., 2009) (eFig. 44.1). In utero ultrasonography has identified abnormal male genitalia, including ambiguous genitalia and penoscrotal transposition (Cheikhelard et al., 2000; Pinette et al., 2003; Vijayaraghavan et al., 2002). More recent ultrasonographic technology, including three-dimensional (3D) ultrasonography, is being used to evaluate the fetal external genitalia, but there are no definitive results suggesting this as an enhanced diagnostic modality (Abu-Rustum and Chaaban, 2009; Bamberg et al., 2011; Verwoerd-Dikkeboom et al., 2008).



EFIG. 44.1 Fetal ultrasound of male genitalia. *P,* Penis; *S,* scrotum.

The understanding of the normal anatomy and embryologic development of the male external genitalia is essential to recognizing and treating penile and scrotal anomalies. Most genital abnormalities noted in neonates do not result in an ambiguous appearance but rather more common conditions such as inconspicuous penis or abnormal penile orientation. The American Academy of Pediatrics (AAP) Committee on Genetics and Sections on Endocrinology and Urology (2000) **published a guide to the normal embryology of the external genitalia and the altered embryology, evaluation, and management of ambiguous genitalia.**

Normal Male External Genitalia

Embryology

The early development of the external genitalia in the two sexes is similar before the ninth week of gestation (Ammini et al., 1997). Understanding factors and sequential steps in normal embryogenesis is fundamental in understanding the pathogenesis of male genital anomalies. **These factors include testosterone synthesis by the Leydig cells of the fetal testis and its enzymatic conversion into dihydrotestosterone (DHT) by 5α-reductase and the presence of androgen receptors able to recognize the androgenic hormones. The influence of DHT on androgen receptors during weeks 9 to 13 of gestation results in the differentiation of the genital tubercle, genital (labioscrotal) folds, and genital swelling into the male structures of the glans penis, penile shaft, and scrotum, respectively.**

The male develops in a proximal-to-distal manner. As the penis forms from the elongation and enlargement of the phallus, the lateral walls of the urethral groove form from the ventrally located genital folds, which then fuse in the midline. The long-held theory that the glanular urethra forms from the ingrowth of surface epithelium has been challenged by evidence suggesting that it is a result of the fusion of the urethral plate (Ammini et al., 1997; Glenister, 1921). The scrotum forms through the inferomedial migration and midline fusion of the genital folds as delineated by the scrotal raphe. **In females and in males with abnormalities in testosterone and/or DHT production, 5α-reductase deficiency, or androgen-receptor insufficiency, the genital tubercle, genital folds, and genital swellings passively become the clitoris, labia minora, and labia majora, respectively.**

Penile Length and Tanner Classification

Penile length significantly increases with gestational age (6 mm at 16 weeks to 26.4 mm at 38 weeks) (Johnson and Maxwell, 2000; Zalel et al., 2001) and during the first 3 months of life. The latter growth is a result of an increase in Leydig cell production of testosterone caused by the loss of the inhibitory effect of maternal estrogens on the fetal pituitary at birth, thereby causing a surge in gonadotropins (minipuberty). During the remainder of childhood, penile length increases more slowly until adolescence, when the length extensively increases again until the final size is reached. **The normal penile size in a full-term male neonate is 3.5 ± 0.7 cm in the stretched length and 1.1 ± 0.2 cm in diameter compared with 13.3 ± 1.6 cm at adulthood.** The penile stretched lengths (measured from meatus to penopubic junction) from birth to adulthood are listed in Table 44.2. Sharony et al. (2012) demonstrated a positive correlation between prenatal penile length measurements and postnatal measurements.

TABLE 44.2

Stretched Penile Length (cm) in Normal Male Subjects

AGE	MEAN ± SD	MEAN − 2.5 SD
Neonate, 30-wk gestation	2.5 ± 0.4	1.5
Neonate, 34-wk gestation	3.0 ± 0.4	2.0
0–5 mo	3.9 ± 0.8	1.9
6–12 mo	4.3 ± 0.8	2.3
1–2 yr	4.7 ± 0.8	2.6
2–3 yr	5.1 ± 0.9	2.9
3–4 yr	5.5 ± 0.9	3.3
4–5 yr	5.7 ± 0.9	3.5
5–6 yr	6.0 ± 0.9	3.8
6–7 yr	6.1 ± 0.9	3.9
7–8 yr	6.2 ± 1.0	3.7
8–9 yr	6.3 ± 1.0	3.8
9–10 yr	6.3 ± 1.0	3.8
10–11 yr	6.4 ± 1.1	3.7
Adult	13.3 ± 1.6	9.3

Tanner stages are a set of recognizable changes that occur to pubic hair, penis, and testes during puberty that are helpful in evaluating patients (Table 44.3). The stages range from preadolescent penis and testes with no pubic hair (stage 1) to adult-size penis and scrotum with adult pubic hair distribution (stage 5).

TABLE 44.3

Tanner Classification of Sexual Maturity Stages in Boys

STAGE	**PUBIC HAIR**	**PENIS**	**TESTES**
1	None	Preadolescent	Preadolescent
2	Scanty, long	Slight enlargement; slightly pigmented	Enlarged scrotum, pink, texture altered
3	Darker, starts to curl, small amount	Longer	Larger
4	Resembles adult type but less in quantity; coarse, curly	Larger; glans and breadth increase in size	Larger, scrotum dark
5	Adult distribution, spread to medial surface of thighs	Adult size	Adult size

Data from Tanner JM: *Growth at adolescence,* ed 2, Oxford, UK, 1962, Blackwell Scientific Publications.

Penile Anomalies

Prepuce (Foreskin)

Phimosis and Paraphimosis

At birth, a physiologic phimosis (Fig. 44.2A) with either partial or complete inability to retract the prepuce exists because of natural adhesions between the glans and inner preputial skin and/or a preputial ring. Two factors are involved in the separation of the prepuce from the glans: (1) accumulation of smegma (epithelial debris) under the prepuce during the first 3 to 4 years of age and (2) intermittent penile erections. Preputial retractability increases with age, with 90% of uncircumcised boys 3 years of age with completely retractable prepuces and less than 1% by 17 years of age with phimosis (Kayaba et al., 1996; Oster, 1968). Thus primary phimosis commonly resolves during childhood. Secondary phimosis may result from several causes, including forceful retraction and balanitis xerotica obliterans (BXO). Forceful preputial retraction should be discouraged to avert cicatrix formation.

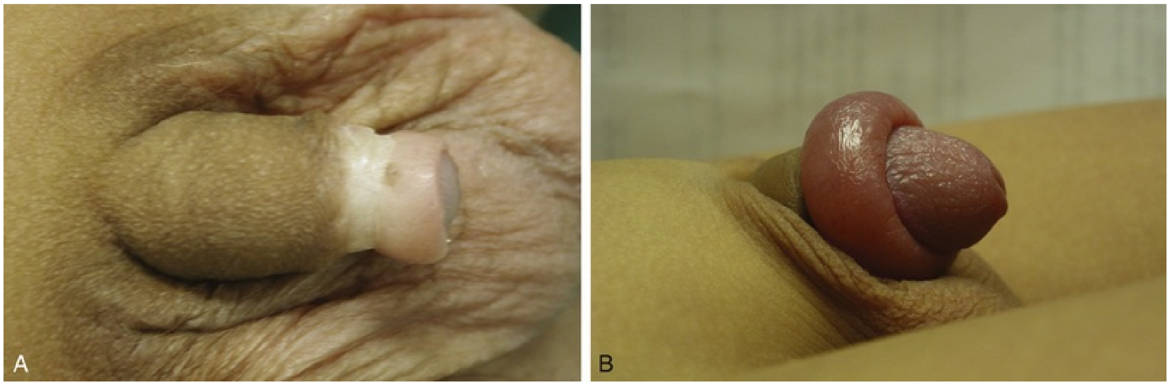

FIG. 44.2 Conditions associated with the uncircumcised penis. (A) Phimosis caused by a preputial ring. (B) Paraphimosis with associated entrapped prepuce behind the glans penis.

Conditions associated with the uncircumcised penis include paraphimosis, infection, urinary tract infection (UTI), and cancer. Paraphimosis (Fig. 44.2B), the entrapment of the prepuce behind the glans penis, can result in gangrene if not reduced in a timely fashion by manipulation, dorsal slit procedure, or circumcision. Severe edema of the foreskin occurs within several hours, depending on the tightness of the tip of the foreskin, making reduction more difficult. In most cases, manual compression of the glans with placement of distal traction on the edematous foreskin allows reduction of the paraphimotic ring. Other treatments include application of an iced glove for 5 minutes, application of granulated sugar for 1 to 2 hours, and placement of multiple punctures in the edematous skin (Mackway-Jones and Teece, 2004).

Indications to enhance preputial retractability include persistent primary phimosis, secondary phimosis, balanitis, posthitis (i.e., inflammation of the prepuce), BXO, and UTIs. Several topical corticosteroid creams with different regimens have been successfully used to treat phimosis with a relatively small number of side effects. Palmer and Palmer (2008) compared the efficacy of two different topical betamethasone (0.05%) treatment regimens (twice daily for 30 days or three times daily for 21 days) and found an 84.5% and 87% response rate, respectively. The response of the prepuce using topical steroids may be seen within 2 weeks (Reddy et al., 2012). Failure to respond to topical steroids (about 15%) may be related to the histologic observation that there is increased density of collagen and decreased density of elastic in the prepuce (Favorito et al., 2012).

Circumcision

Circumcision dates back more than 6000 years, with the oldest documented evidence thought to date to sixth dynasty (2345–2181 BCE) tomb artwork in Egypt. Since that time, different religions, countries, and cultures have adopted various views on circumcision (Palmer, 2009a). Many theories have been proposed regarding the origin of circumcision, including as a religious sacrifice, a rite of passage, an aid to hygiene, a way to differentiate cultural groups, and a method to discourage masturbation.

Elective circumcision in the neonate remains controversial. The AAP has historically weighed in on this subject. In 1989 the AAP concluded that neonatal circumcision offered potential medical benefits and advantages as well as disadvantages and risks, which should be explained to parents (AAP Task Force on Circumcision, 1989). In 1999 the AAP updated its policy statement (AAP Task Force on Circumcision, 1999; Lannon et al., 2000) emphasizing the importance of local anesthesia for the procedure. Most recently, the AAP stated, **“Although health benefits [significant reductions in the risk of UTI, risk of heterosexual acquisition of human immunodeficiency virus, and the transmission of other sexually transmitted infections] are not great enough**

to recommend routine circumcision for all male newborns, the benefits of circumcision are sufficient to justify access to this procedure for families choosing it and to warrant third-party payment for circumcision of male newborns" (AAP Task Force on Circumcision, 2012).

There are several techniques and devices for performing neonatal circumcision, including the Gomco clamp, Mogen clamp, and Plastibell device. There should be complete separation of the prepuce from the glans and complete inspection of the meatus and the corona to confirm the absence of anomalies, including hypospadias. **When neonatal circumcision is performed, local anesthesia is recommended.** Available options include the topical application of a cream containing eutectic mixture of local anesthetic (EMLA; lidocaine and prilocaine), a dorsal penile nerve block, and a penile ring block (Hardwick-Smith et al., 1998). Randomized controlled trials demonstrate the superiority of a dorsal penile nerve block to EMLA cream (Howard et al., 1999; Taddio et al., 2000), and prilocaine in the EMLA cream poses a low risk for methemoglobinemia (Couper, 2000). Typically, older infants and children are circumcised under general anesthesia, rather in the office, using freehand resection techniques.

Circumcision should not be performed in neonates with other penile conditions that require surgical correction using the intact skin. These conditions include hypospadias, penile curvature, dorsal hood deformity, buried penis, and webbed penis (see the corresponding sections). Other conditions commonly seen in neonates that could cause the penile skin to be pushed forward should be taken into consideration, such as large hydroceles or inguinal hernias; these conditions increase the risk of developing secondary phimosis, buried penis, and trapped penis, and thus circumcision should be deferred. A known coagulopathy in a neonate is another contraindication. Performance of circumcision in the neonatal intensive care unit is associated with more complications (Srinivasan et al., 2015).

Circumcision has several potential benefits, including the prevention of penile cancer, UTIs, sexually transmitted diseases including human immunodeficiency virus (HIV) infection, and phimosis, as well as lessening of the risk of balanitis. The allegation that neonatal circumcision can lead to sexual dysfunction is not supported by long-term studies (Bleustein et al., 2005; Fink et al., 2002). Schoen et al. (2006a) determined that neonatal circumcision has a cost benefit compared with postneonatal circumcision, including procedure charges and reduction in future health care costs.

Carcinoma of the penis develops almost exclusively in men who are not circumcised at birth. Phimosis is a significant risk factor (Tsen et al., 2001). Schoen et al. (2000b) reported that of 89 men in a large health maintenance organization with invasive penile cancer, only 2 (2%) had been circumcised at birth. Furthermore, of 116 men with penile carcinoma in situ, 16 (14%) had had a neonatal circumcision.

Uncircumcised neonates and infants are predisposed to UTIs (Singh-Grewal et al., 2005). In a study of 100 neonates with a UTI, Ginsburg and McCracken (1982) found that only 3 (5%) of the 62 boys who developed a UTI were circumcised. Subsequently, Wiswell et al. (1985) studied more than 2500 male infants and found that 41 had symptomatic UTIs; 88% of these infants were uncircumcised. Uncircumcised boys were almost 20 times more likely than circumcised neonates to develop a UTI. Other studies of larger groups of infants confirm these reports (Wiswell, 2000; Zorc et al., 2005) and demonstrate that neonatal circumcision is less costly than treating UTIs in uncircumcised boys (Schoen et al., 2000a). The increased risk seems to affect boys at least through 5 years of age (Craig et al., 1996), and the incidence of epididymitis is also reduced (Bennett et al., 1998). The increased risk of UTIs can be attributed to colonization of the prepuce by urinary pathogens (Bonacorsi et al., 2005; Gunsar et al., 2004). It has been calculated that it takes 111 neonatal circumcisions to prevent one UTI (Singh-Grewal et al., 2005). However, Shim et al. (2009) evaluated 190 infants with confirmed normal urinary systems and diagnosed with their first febrile UTI for recurrent UTI during the following year. Thirty-four percent of infants with persistent nonretractile prepuces developed recurrent UTI, compared with 17.6% of infants with retractile prepuces.

Whether circumcision reduces the risk of sexually transmitted diseases has been controversial. Several recent large series have demonstrated reduced incidence of HIV infection among men, with a protective effect of 60% (Bailey et al., 2007; Gray et al., 2007). However, a recent study compared HIV transmission with HIV-uninfected female partners among 922 uncircumcised, HIV-infected, asymptomatic men, of whom 474 underwent immediate circumcision and 448 remained uncircumcised (Wawer et al., 2009). After 24 months of follow-up, 18% and 12% of women acquired HIV, respectively, concluding that circumcision of HIV-infected men did not reduce HIV transmission to female partners. It has been reported that circumcision may reduce the risk of ulceration, bacterial vaginosis, and trichomoniasis in female partners (Gray et al., 2009).

Several clinical trials of the effect of circumcision on the prevention of human papillomavirus (HPV) infection, herpes simplex virus type 2 (HSV-2) infection, and other sexually transmitted diseases (Auvert et al., 2009; Nielson et al., 2009; Tobian et al., 2009) have been done. Tobian et al. (2009) evaluated 5534 HIV-negative, uncircumcised males, with 3393 being HSV-2 seronegative at enrollment. Of the 3393 men, 1684 underwent immediate circumcision and 1709 were not circumcised to evaluate HSV-2 and HPV transmission. At 24 months' follow-up, HSV-2 seroconversion was 7.8% and 10.3%, respectively, whereas prevalence of high-risk (carcinogenic) HPV genotypes was 18.0% and 27.9%, respectively. This study underscores the benefit of circumcision in reducing the incidence of HSV-2 infection and the prevalence of HPV infection.

Key Points: Circumcision

- Primary phimosis resolves spontaneously in the vast majority of boys; fewer than 1% of 17-year-old boys have a phimotic prepuce.
- Indications to facilitate preputial retractility include persistent primary phimosis, secondary phimosis, balanitis, posthitis, BXO, and UTI.
- The American Academy of Pediatrics acknowledges the potential health benefits of the circumcised penis, thus warranting access to circumcision for families choosing it and endorsing third-party payment for circumcision of male newborns.
- Local or topical anesthetics should be administered for circumcisions performed in the neonatal period.
- Circumcisions should be deferred in the presence of other penile abnormalities detected in the newborn period that may require surgery.
- Health benefits of circumcision include reduction in rates of penile cancer, and sexually transmitted diseases including HIV, UTIs, balanitis, and phimosis.
- Topical application of corticosteroids can relax the phimotic ring in 70% to 80% of cases.

Circumcision Complications.

The risk of complications after circumcision is 0.2% to 5% (Baskin et al., 1996; Ben Chaim et al., 2005; Christakis et al., 2000). Complications can occur immediately or months to years after a circumcision. **The most common complication is bleeding, which occurs in 0.1% and is more common in older children.** Bleeding is usually localized from the frenulum or, less frequently, from a large blood vessel on the penile shaft or from a skin edge between the suture. Although bleeding is usually self-limited or may require compression, occasionally cautery with an ophthalmic cautery or silver nitrate stick or a suture may be necessary. Wound infection is a rare complication, but antibiotic ointment (e.g., bacitracin) use after circumcision usually prevents its development. Penile degloving caused by excess skin removal or the edges of the penile skin not adhering to the mucosal collar can occur after circumcision. The penile shaft usually epithelizes, bridging the defect without any intervention other than the use of antibiotic ointment to the denuded region and warm baths to prevent eschar formation. Immediate suturing of the skin edges and skin grafting are not recommended to bridge the gap.

Penile Skin Complications.

The amount of penile skin excised can also lead to complications after circumcision. Insufficient or asymmetrical prepuce excision can result in health, cosmetic, and social dilemmas for the parents and child, especially as the child gets older (Fig. 44.3A). **Unlike neonatal circumcision, circumcision revision requires general anesthesia.** Several techniques have been described (Brisson et al., 2002; Ching and Palmer, 2008a; Redman, 1995). Excessive skin excision can result in penile chordee, torsion, and lateral deviation. These conditions, if necessary to repair, may require penile skin flaps or Z-plasty for closure. Excessive skin removal can also result in a trapped penis from a cicatricial scar. The trapped penis can be managed with betamethasone (Palmer et al., 2005), vertical relaxation incision, and formal repair using penile skin flaps or Z-plasty. The use of 0.05% betamethasone in conjunction with manual retraction in children with a trapped penis resulting from a dense cicatrix of the residual foreskin distal to the glans has a 79% success rate in softening of the cicatrix with easy exposure of the glans or mild persistence of the cicatrix amenable to vertical relaxation incision (Palmer et al., 2005).

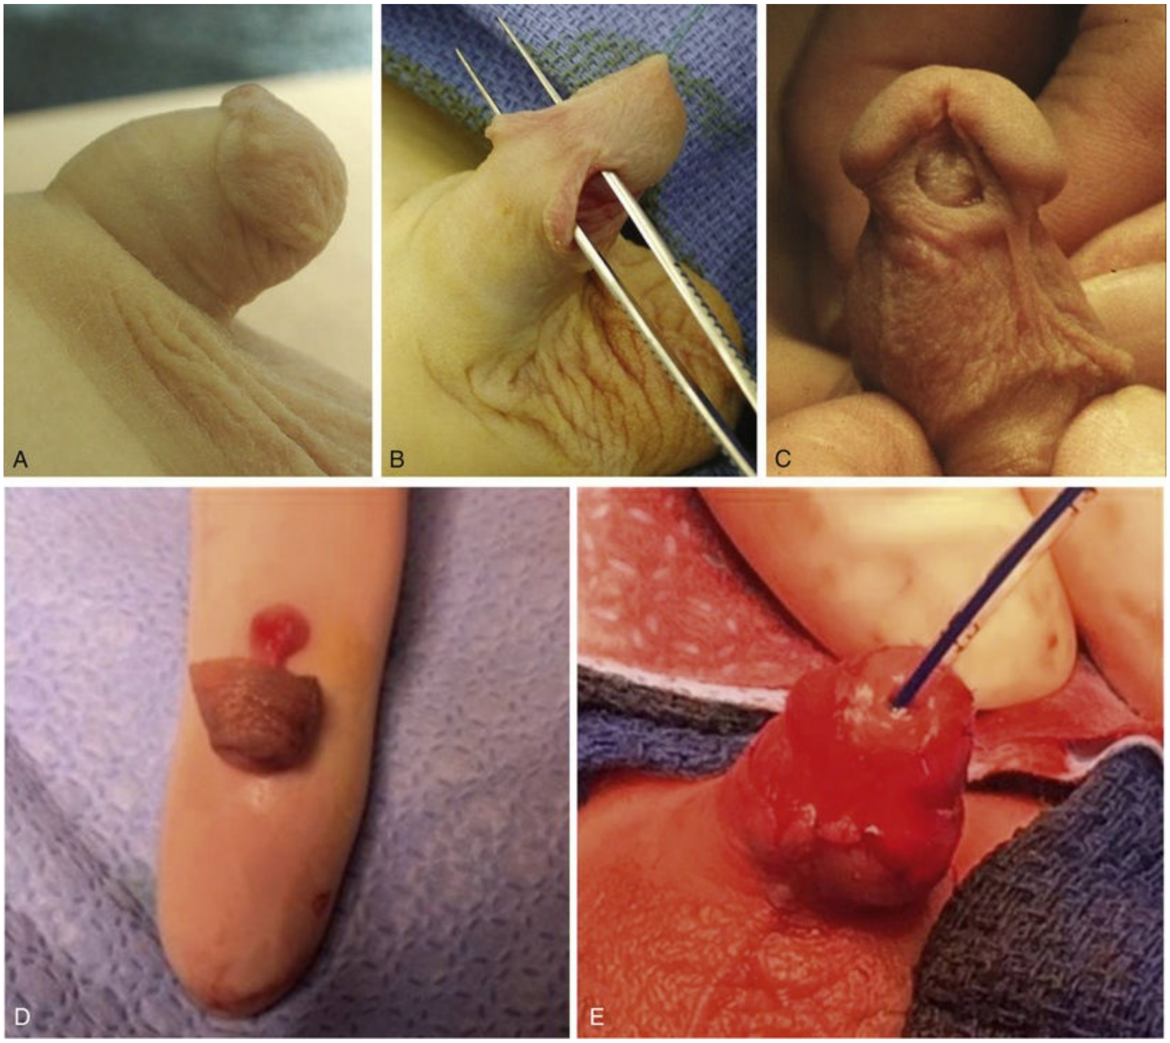

FIG. 44.3 Complications associated with circumcision. (A) Asymmetrical redundant penile skin. (B) Penile skin bridge. (C) Urethral and glanular resection. (D) Flap of amputated glans attached to prepuce. (E) Reattached flap of glans amputated during circumcision.

Glanular Adhesions and Skin Bridges.

Glanular adhesions and skin bridges, attachments of the glans and penile shaft, are common complications associated with circumcision and are usually noticed by the caregiver or primary medical provider. **Both can occur in the well-circumcised penis and are usually the result of the physiologic retraction of the penis caused by a suprapubic fat pad and diaper irritation of the penis.** Glanular adhesions are attachments between the inner prepuce or circumcision incision line attaching to the glans, with an incidence decreasing with age because of epithelial separation of the adhesions (71% of infants, 28% of 1- to 5-

year-olds, 8% of 1- to 9-year-olds, and 2% of children older than 9 years) (Ponsky et al., 2000; Van Howe, 1997). **Persistent adhesions can be lysed in the office with the application of a topical analgesic such as EMLA cream or Pain Ease** (Gebauer Company, Cleveland, OH) **(1,1,1,3,3-pentafluoropropane and 1,1,1,2-tetrafluoroethane)** (Palmer, 2009b). **Use of low-dose corticosteroids has been relatively unsuccessful in lysing adhesions.** Skin bridges (Fig. 44.3B) are epithelized adhesions that can lead to penile chordee and torsion, which can be excised in the office with the application of an analgesic (Palmer, 2009b) or in the operating room when the bridges are broad or thick and may require suturing of the glanular and shaft defects.

The most common acquired cystic lesion of the penis is entrapped smegma under the unretractable prepuce or under the glanular adhesions. The mass may appear yellow because of smegma. Release of the smegma occurs with resolution of the adhesions, either spontaneously or with manual lysis of adhesions.

Meatal Stenosis.

Meatal stenosis occurs in children almost only after circumcision during infancy (Fig. 44.4A). It can be congenital, occurring primarily in neonates with hypospadias, or acquired. **The normal urethral meatus is 10 Fr before 4 years of age, 12 Fr from 4 to 10 years of age, and 14 Fr after 10 years of age** (Litvak et al., 1976)**; this can be calibrated with a bougie à boule or sound.** There are several proposed causes of secondary meatal stenosis. One theory purports that after disruption of the normal adhesions between the prepuce and glans and removal of the foreskin, a significant inflammatory reaction ensues, resulting in a severe meatal inflammation and cicatrix formation. Other theories include frenular devascularization or chronic meatitis from diaper irritation of the exposed, unprotected meatus (Hensle, 1996; Persad et al., 1995). BXO is another cause of meatal stenosis (see following). A relatively small percentage of children will develop symptomatic meatal stenosis after neonatal circumcision. **Symptoms include (1) urinary stream deviation in an upward direction resulting from a meatal baffle** (Fig. 44.4B) **or ventral web located at the inferior of the meatus, (2) a narrow, high-velocity stream, and (3) penile pain at the initiation of micturition.** Urinary tract imaging usually does not reveal any obstructive changes in the urinary tract without other urologic issues but may be indicated for associated UTI or urinary incontinence. Meatotomy or meatoplasty to treat secondary meatal stenosis can be performed in the office with the use of topical lidocaine and prilocaine (EMLA) (Cartwright et al., 1996) or with general anesthesia by making a ventral incision long enough to create a normal meatal caliber. The suturing of the urethral mucosa to the glans with fine, rapidly absorbable sutures tends to reduce the risk of recurrence. An alternative but equally efficacious technique involves meatal tailoring using clamps without the need for suture (Cubillos et al., 2012).

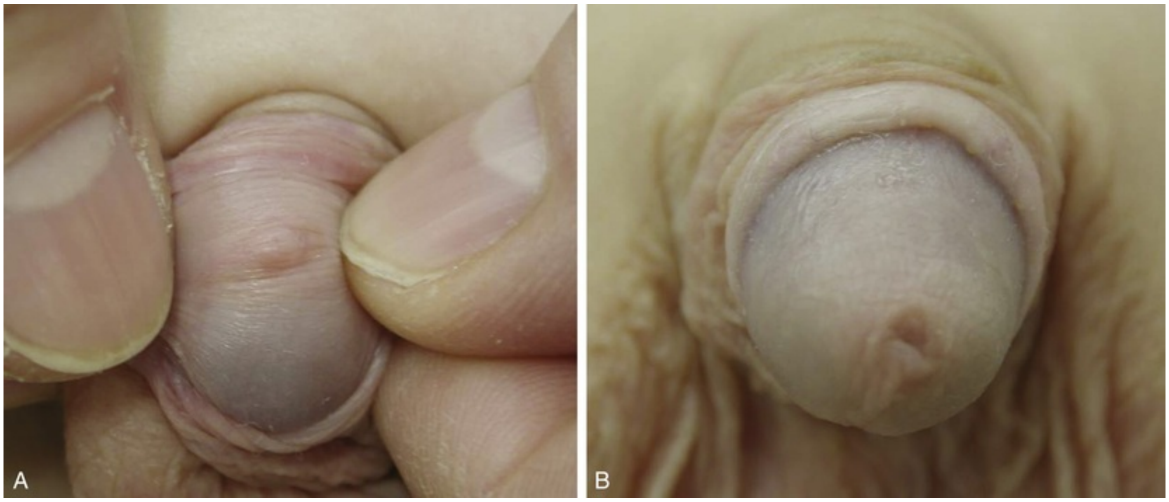

FIG. 44.4 Meatal complications associated with circumcision. (A) Meatal stenosis. (B) Meatal baffle.

Penile Trauma.

The most serious complications associated with circumcision are penile trauma, including urethral injury, excision of the glans and/or penile shaft, and penile necrosis (see Fig. 44.3C). Urethral injury requires urethroplasty, with the technique dependent on the severity of the excision. **Excision of the glans can be repaired by suturing the excised tissue back to the penis, often without the need for microscopic repair** (Sherman et al., 1996), **yielding good results when performed within 8 hours** (see Fig. 44.3D and E). Penile necrosis can result from thermal injury from several causes, including cautery contacting the metal ring applied to the prepuce being excised or the inappropriate use of lasers to perform a circumcision. Several options are available without ideal outcomes, including penile reconstruction and female gender reassignment with bilateral orchiectomy (Bradley et al., 1998; Gearhart and Rock, 1989). Although the cosmetic and functional results of phallic reconstruction have advanced, they are still being refined (De Castro et al., 2007; Monstrey et al., 2009). The issues with gender reassignment can include these children growing up with a male identity believed to result from in utero and neonatal androgen imprinting (Diamond, 1999; Diamond and Sigmundson, 1997; Reiner, 1996).

Balanitis Xerotica Obliterans.

Lichen sclerosus et atrophicus, or BXO, is a chronic infiltrative and cicatrizing skin condition resulting in pathologic phimosis (Chalmers et al., 1984; Fig. 44.5). **BXO can affect the glans and meatus as well as the urethra.** The inability to retract the prepuce is the common presentation at puberty and is rare in children younger than 5 years of age (Oster, 1968). Other symptoms include local infection, irritation, discomfort after micturition, bleeding, and occasionally acute urinary retention or urinary incontinence (Bale et al., 1987). Older patients and those with BXO involving the meatus may have a more severe clinical course (Gargollo et al., 2005). The cause of BXO remains unknown without an identified viral or bacterial cause or a familial predisposition. The association of BXO and penile cancer in children is also not established.

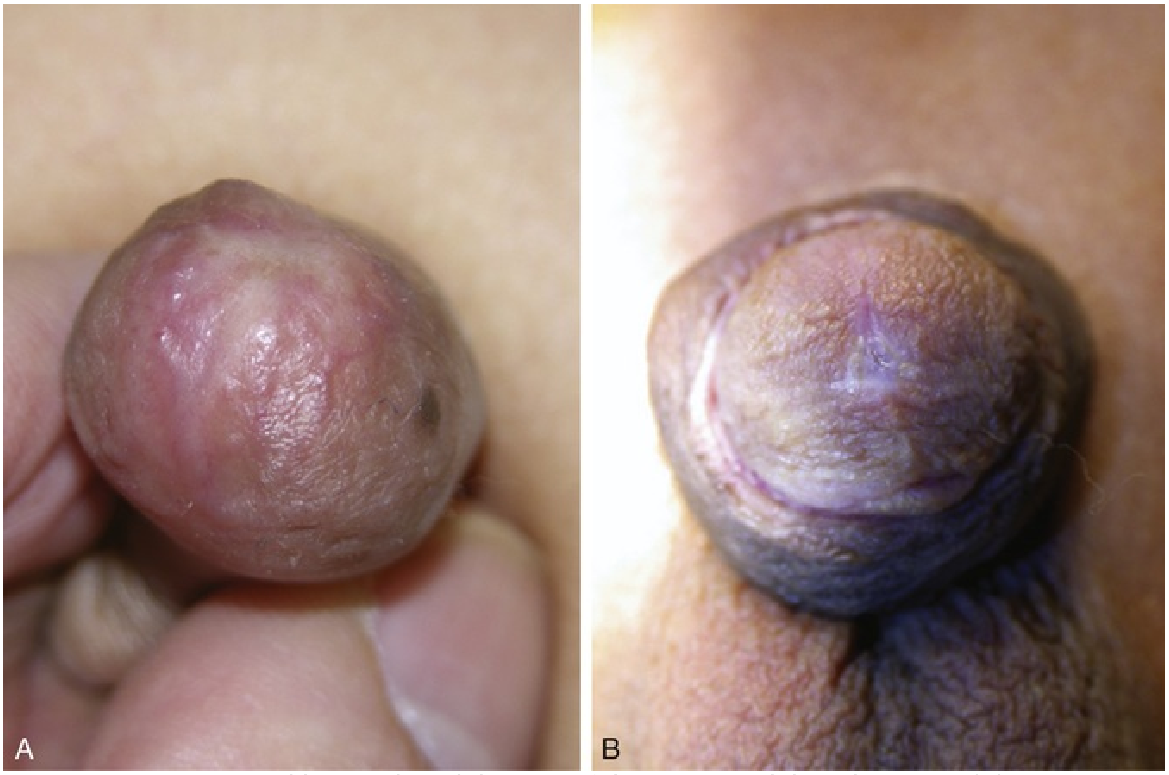

FIG. 44.5 Balanitis xerotica obliterans of the prepuce (A) and meatus (B). (Courtesy Warren Snodgrass, MD.)

Treatment of BXO includes medical and surgical options. The use of topical corticosteroids has had limited benefit to treat mild BXO of the prepuce with minimal scar formation (Vincent and Mackinnon, 2005). **Circumcision is the preferred treatment along with meatotomy or meatoplasty in cases of meatal involvement.** Children with meatal involvement should be observed postoperatively because of the risk of recurrent meatal stenosis, but 20% may require subsequent meatal surgery (Homer et al., 2014). A prepuce-sparing approach was described by Wilkinson et al. in 104 uncircumcised boys for whom triradiate preputial incisions and injection of triamcinolone intralesionally were performed. This resulted in 81% having a fully retractile prepuce without macroscopic evidence of BXO; 13% developed recurrent symptoms or BXO requiring circumcision or repeat foreskin preputioplasty. The development of meatal stenosis occurred in significantly fewer boys than in those who underwent initial circumcision (Wilkinson et al., 2012).

Key Points: Circumcision Complications

- The risk of complications from circumcision is 0.2% to 5%; bleeding is the most common.
- Circumcision revisions require the child to be under general anesthesia.
- Meatal stenosis occurs only in the circumcised penis.
- Topical corticosteroids fail to resolve penile adhesions.
- BXO is a chronic infiltrative and cicatrizing skin condition.

Abnormal Penile Number

Aphallia

Penile agenesis results from failure of development of the genital tubercle (Roth et al., 1981; Fig. 44.6). The disorder is rare, with an estimated incidence of 1 in 10 million to 30 million births. **The karyotype almost always is 46,XY, and the usual appearance is that of a well-developed scrotum with descended testes and an absent penile shaft.** The anus is usually displaced anteriorly. The urethra often opens at the anal verge adjacent to a small skin tag or may open into the rectum. The incidence of stillbirth or neonatal death is approximately one in three cases (Gilbert et al., 1990).

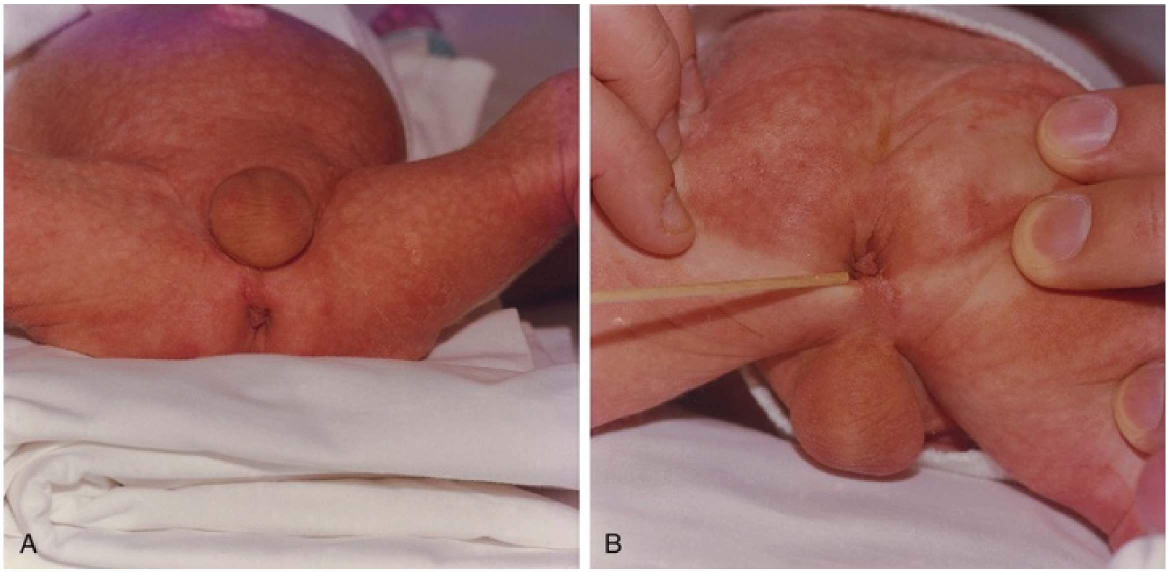

FIG. 44.6 (A) Neonate with aphallia. (B) Urethral meatus at skin tag on anal verge.

Associated malformations are common and include cryptorchidism, vesicoureteral reflux, horseshoe kidney, renal agenesis, imperforate anus, and musculoskeletal and cardiopulmonary abnormalities (Evans et al., 1999; Friedman et al., 2016c; Skoog and Belman, 1989). The connection between the genitourinary and gastrointestinal tract is variable. Skoog and Belman (1989) reviewed 60 reports of aphallia and found that the more proximal the urethral meatus, the greater the likelihood of neonatal death and the incidence of other anomalies. In this study 60% of patients had a postsphincteric meatus located on a peculiar appendage at the anal verge; these patients had the highest survival rate (87%) and the lowest incidence of other anomalies (1.2 per patient). Of those patients studied, 28% had presphincteric urethral communications (prostatorectal fistula), and there was a 36% neonatal mortality rate. Twelve percent had urethral atresia and a vesicorectal fistula for drainage. This group had the highest incidence of other anomalies and a 100% mortality rate. Friedman et al. (2016) noted that aphallia should be considered in girls with severe urinary tract dysplasia and genital ambiguity and recommended imaging of the urinary tract (ultrasound cystography).

Children with this lesion should be evaluated immediately with a multidisciplinary approach. Testing should include a karyotype and other

appropriate studies to detect associated malformations of the urinary tract or other organ systems. Magnetic resonance imaging (MRI) may be beneficial in determining the severity of the defect (Lapointe et al., 2001).

Advances in neophallus reconstruction offer these children an alternative to gender reassignment. As a male, the patient would potentially be fertile; although current advances in phalloplasty and urethroplasty allow for sexual and voiding function (De Castro et al., 2013; Garaffa et al., 2014; Oliveira et al., 2016), reproductive function is unknown. **A recommendation to perform gender reassignment should be made carefully and only after full evaluation by a multidisciplinary team and parental counseling.** Some of these patients have a male gender identity despite reconstruction as a female, presumably because of in utero or postnatal sex steroid imprinting (Diamond, 1999; Diamond and Sigmundson, 1997; Reiner, 1996). Gender reassignment involves orchiectomy and feminizing genitoplasty in the neonatal period (Bruch et al., 1996; Gluer et al., 1998) and neovagina at a later age. Urinary tract reconstruction with simultaneous construction of an intestinal neovagina through a posterior sagittal and abdominal approach in patients with penile agenesis has been described (Hendren, 1997; Hensle and Dean, 1992).

Diphallia

Duplication of the penis (Fig. 44.7) **is a rare anomaly with an incidence of 1 in 5 million live births** (Hollowell et al., 1977) **and has a range of appearances from a small accessory penis to complete duplication** (Gyftopoulos et al., 2002). In some cases, each phallus has only one corporal body and urethra, whereas others seem to be a variant of twinning, with each phallus having two corpora cavernosa and a urethra. The penises are usually unequal in size and situated adjacently. Other associated anomalies are common, including hypospadias, bifid scrotum, bladder duplication, renal agenesis or ectopia, and diastasis of the pubic symphysis (Maruyama et al., 1999). Anal and cardiac anomalies are also common. **Evaluation should include imaging of the entire urinary tract, including a renal ultrasound and voiding cystourethrogram.** Ultrasonography and MRI can also be done to assess penile development (Lapointe et al., 2001; Marti-Bonmati et al., 1989). The cause has not been delineated. Treatment must be individualized, with consideration of the associated anomalies with the goal of attaining a satisfactory functional and cosmetic result (Dean and Horton, 1991).

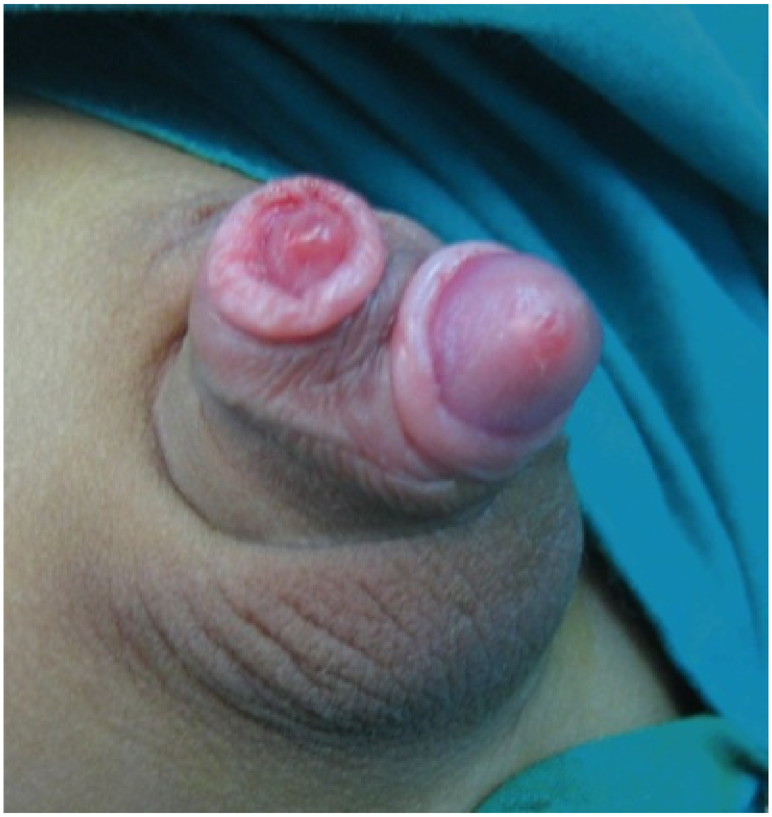

FIG. 44.7 Child with diphallia. Both phalluses sat on a common mons but had separate urethras.

Inconspicuous Penis

An inconspicuous penis is one that appears to be small but with normal stretched penile length measured from the pubic symphysis to the tip of the glans (see Table 44.2) **and normal diameter of the penile shaft** (Bergeson et al., 1993). This condition can be congenital or acquired and is usually of great concern for parents. Several entities are included in this disorder, including buried penis, trapped penis, and webbed penis (Palmer and Kogan, 1995). **These conditions must be differentiated from micropenis, in which the penis is abnormally small.** When an infant has an inconspicuous penis, evaluation is necessary for proper treatment and counseling of the family as to whether the penis is or is not normal.

Buried Penis

A buried penis, also referred to as a *hidden* or *concealed penis*, is a form of inconspicuous penis (Cromie et al., 1998). A buried penis is a normally developed penis that is hidden by the suprapubic fat pad. **This condition can be classified into three categories based on cause of the concealment** (Casale et al., 1999; Maizels et al., 1986): **(1) poor penopubic and/or penoscrotal fixation of the skin at the base of the penis, (2) obesity, and (3) a trapped penis from cicatricial scarring after penile surgery, typically a circumcision.**

The congenital form of buried penis is believed to result from the inelasticity of the dartos fascia, which normally allows the penile skin to slide freely on the deep layers of the shaft, with restricted extension of the penis because the penile skin is not anchored to the deep fascia (Fig. 44.8). The acquired form from obesity typically seen in older children and adolescents is caused by abundant fat on the abdominal wall hiding the penile shaft. The other acquired form, a trapped penis, results from embedding of the penis in the suprapubic fat pad from scar formation over the glans. This deformity may occur after neonatal circumcision in an infant with significant scrotal swelling as a result of a hernia or hydrocele or after routine circumcision in an infant with a webbed penis. Also, in some neonates the penile shaft seems to retract naturally into the scrotum, and if circumcision is performed in this situation, the skin at the base of the penis may form a cicatrix over the retracted phallus. This condition should be differentiated from a transient buried penis resulting from a large suprapubic fat pad noted in early childhood that resolves with increased age and ambulation (Eroglu et al., 2009).

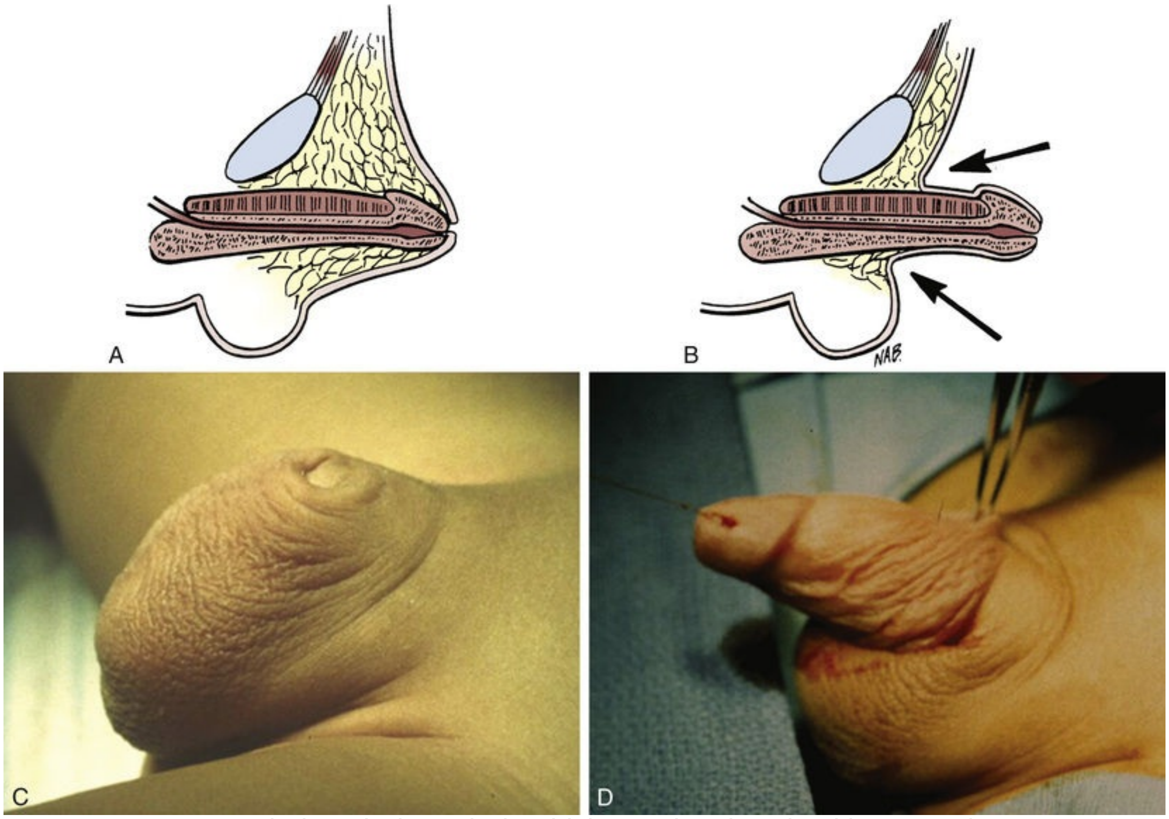

FIG. 44.8 Buried penis (A and C), which may be visualized by retraction of the skin lateral to the penile shaft (B and D).

On examination, a buried penis must be differentiated from a micropenis with an abnormal penile stretched length. The clinician should determine whether the glans can be exposed by retracting the skin covering the glans (see Fig. 44.8). If so, it remains the surgeon's judgment whether correction is warranted. However, if the penis is trapped by physiologic phimosis in the uncircumcised penis or cicatricial scarring (Fig. 44.9A) in the circumcised penis, this increases the chance of difficulty voiding, maintaining proper hygiene, balanitis, UTIs, and psychosocial issues (Fig. 44.9B; Kon, 1983).

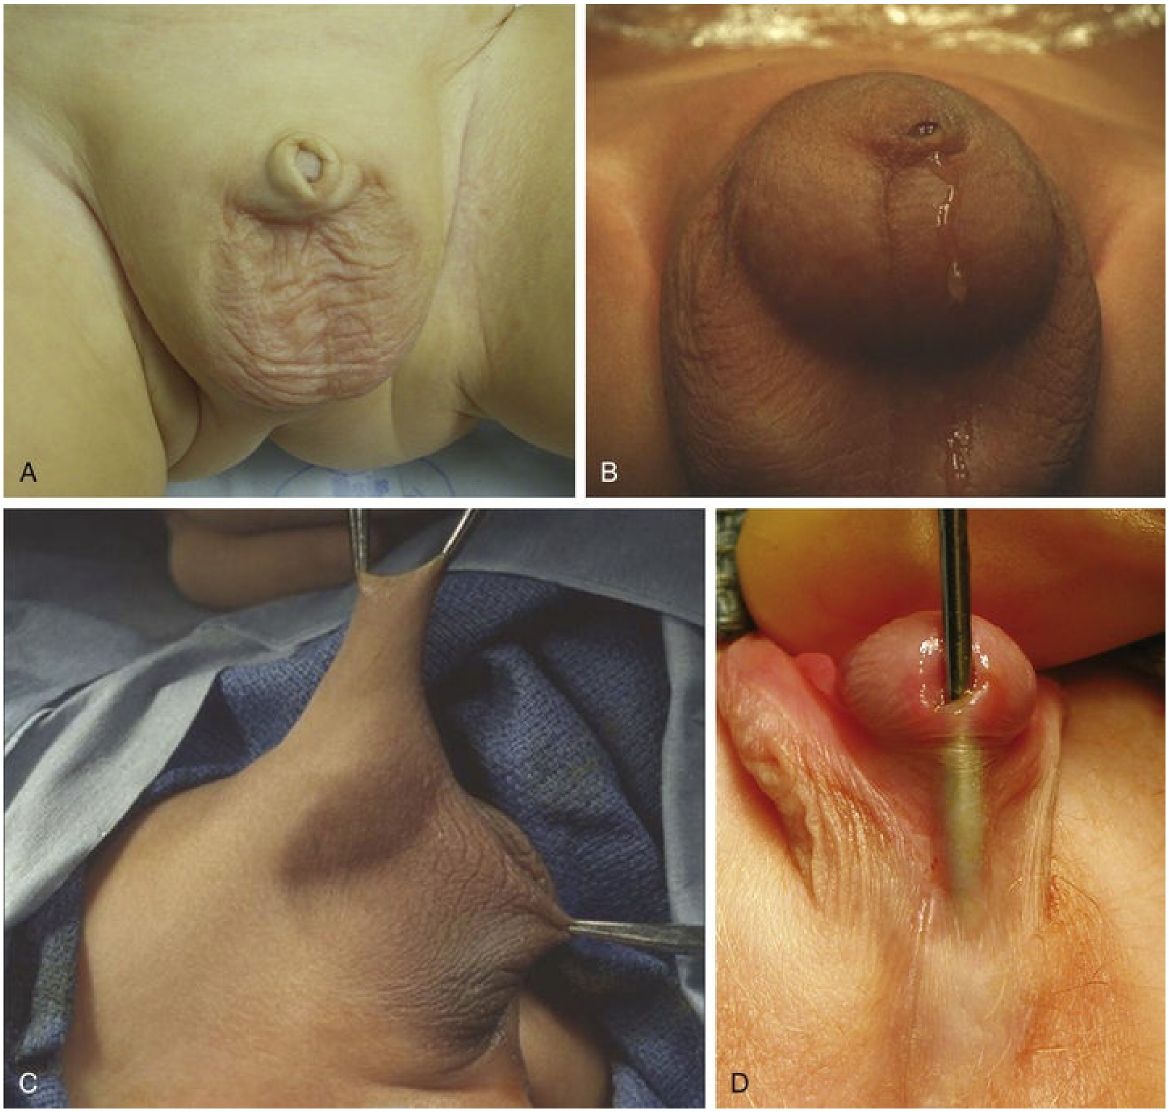

FIG. 44.9 Inconspicuous penis. (A) Trapped penis by cicatricial scarring resulting from neonatal circumcision. (B) Urine pooling caused by cicatricial scarring, increasing susceptibility to urinary tract infections. (C) Penoscrotal web resulting in a webbed penis. (D) Webbed penis with hypoplastic distal urethra.

The treatment options for children with buried penis are centered on the anatomic cause. Patients with buried penis secondary to obesity should have the underlying condition treated with referral back to the primary care provider for a weight loss and exercise program. The child should then be reevaluated to assess whether surgery is needed. Young children with secondary cicatricial scarring after penile surgery can be managed with forceful dilation of the cicatrix with a fine hemostat in the office after the application or injection of analgesic. Another option is the combination of topical betamethasone and manual retraction

(Palmer et al., 2005), which yielded complete resolution in the majority of boys or released the closing cicatrix, allowing for a simple incision of the phimotic ring; this reduced the need for formal surgical repair by 79%. If topical corticosteroid application is ineffective, correction under general anesthesia is necessary, with the usual recommendation of elective repair when the child is at least 6 months of age. The surgical technique is similar to that for the congenital buried penis.

A number of surgical techniques have been described to correct the buried penis (Borsellino et al., 2007; Casale et al., 1999; Elder, 2001; Frenkl et al., 2004; Gillett et al., 2005; Karapetian and Palmer, 2007, Liu et al., 2016; Maizels et al., 1986). The indications and timing for reconstructive surgery are controversial. In moderately severe cases the dysgenic bands of tissue, which are located primarily on the proximal dorsal surface of the shaft of the penis, must be removed. The prepuce should be unfurled and used for ventral skin coverage. In addition, the subcutaneous tissue on the dorsal aspect of the penis should be fixed to the pubic fascia, and then the subcutaneous tissue of the scrotum should be fixed to the ventral aspect of the base of the penile shaft. During correction the surgeon must be careful to avoid injury to the neurovascular bundles (Baskin, 1999; Baskin et al., 2000). Skin coverage can also be accomplished by penoscrotal Z-plasty, lateral penile shaft Z-plasty, island pedicle of ventral preputial skin, or a skin graft. Rarely, in the most severe cases the suspensory ligament of the penis must be divided, the suprapubic fat excised, and the spermatic cords protected. The benefit of liposuction has been reported in severe cases (Maizels et al., 1986; Shenoy et al., 2000). However, this technique should be reserved for adolescent boys because prepubertal boys may lose their fat pad simply with somatic growth.

Webbed Penis

Webbed penis, also known as *penoscrotal fusion*, is a congenital or acquired condition resulting from the scrotal skin extending onto the ventrum of the penis. The congenital form of a penoscrotal web represents an abnormality of the attachment between the penis and the scrotum, whereas the penis, urethra, and remainder of the scrotum are normal (Fig. 44.9C). The acquired condition results from circumcision or other penile surgery, as a result of excessive removal of ventral penile skin.

Although the penoscrotal web is usually asymptomatic, the appearance is often unacceptable. There are several surgical techniques to correct this condition. Similar to the treatment of a buried penis, one technique involves the fixation of the subcutaneous tissue of the scrotum to the ventral aspect of the base of the penile shaft. On occasion, this condition may be corrected by incision of the web transversely, separation of the penis from the scrotum, and closure of the skin vertically. In other cases, a circumferential incision is made 1.5 cm proximal to the coronal sulcus, a Byar preputial skin flap is transferred to the ventral surface of the penis, and the redundant foreskin is excised. In rare cases the distal urethra is hypoplastic, necessitating urethral reconstruction (Fig. 44.9D).

Micropenis

Micropenis is a normally formed penis that is at least 2.5 standard deviations (SD) below the mean size in stretched length for age (Aaronson, 1994; Fig. 44.10). The ratio of the length of the penile shaft to its circumference is usually normal, but occasionally the corpora cavernosa are severely hypoplastic. The testes are usually small and frequently cryptorchid, whereas the scrotum is usually fused and often diminutive.

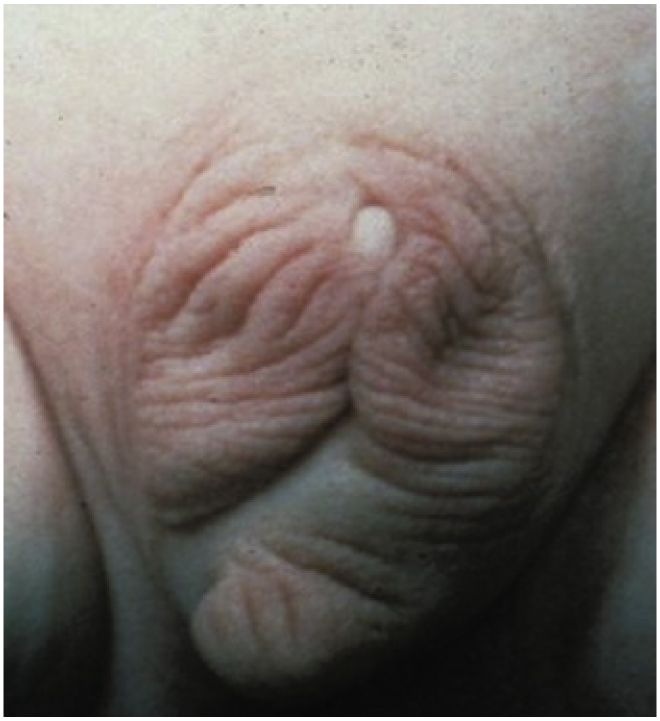

FIG. 44.10 Micropenis resulting from hypogonadotropic hypogonadism.

Stretched penile length correlates more closely with erectile length than does the relaxed penile length and should be compared with standards for penile length (see Table 44.2). Stretched penile length is determined by measuring the penis from its attachment to the pubic symphysis to the tip of the glans. The suprapubic fat pad must be depressed completely for an accurate measurement to be obtained, especially in an obese infant or child. **In general, the penis of a full-term neonate should be at least 1.9 cm long.** One must differentiate buried penis or webbed penis from the micropenis, with the former having a normal penile shaft.

Micropenis results from a hormonal abnormality that occurs after 14 weeks of gestation. Differentiation of the male external genitalia is complete by the 12th week of gestation and requires a normal testis producing testosterone, stimulated by maternal human chorionic gonadotropin (hCG). During the second and third trimesters, growth of the penis occurs under the direction of fetal androgen controlled by the secretion of fetal luteinizing hormone (LH). An abnormality in the production or use of testosterone results in a small penis and hypospadias, whereas a true micropenis often seems to be a consequence of a deficiency of gonadotropic hormones.

The causes of micropenis are many (eBox 44.1) and include isolated gonadotropin defects and generalized endocrinopathies that may be associated with central nervous system defects. **The most common causes of micropenis are hypogonadotropic hypogonadism, hypergonadotropic hypogonadism (primary testicular failure), and idiopathic** (Lee et al., 1980b). Micropenis is often associated with major chromosomal defects, including Klinefelter syndrome (47,XXY) and other X polysomy syndromes, deletions, translocations, and trisomy involving chromosomes 8, 13, and 18 (Aaronson, 1994).

eBox 44.1

Etiology of Micropenis

Deficient Testosterone Secretion

- Hypogonadotropic hypogonadism
  - Isolated, including Kallmann syndrome
  - Associated with other pituitary hormone deficiencies (e.g., CHARGE association)

- Prader-Willi syndrome
    - Laurence-Moon syndrome
    - Bardet-Biedl syndrome
    - Rud syndrome
- Primary hypogonadism
    - Anorchia
    - Klinefelter syndrome and poly X syndrome
    - Gonadal dysgenesis (incomplete)
    - Luteinizing hormone receptor defects (incomplete)
    - Genetic defects in testosterone steroidogenesis (incomplete)
    - Noonan syndrome
    - Down syndrome
    - Robinow syndrome
    - Bardet-Biedl syndrome
    - Laurence-Moon syndrome

Defects in Testosterone Action

- Growth hormone/insulin-like growth factor 1 deficiency
- Androgen receptor defects (incomplete)
- 5α-Reductase deficiency (incomplete)
- Fetal hydantoin syndrome

Developmental Anomalies

- Aphallia
- Cloacal exstrophy

Idiopathic

- Associated with other congenital malformations

Data from Bin-Abbas B, Conte FA, Grumbach MM, et al. Congenital hypogonadotropic hypogonadism and micropenis: effect of testosterone treatment on adult penile size—why sex reversal is not indicated. *J Pediatr.* 134:579, 1999.

The most common cause of micropenis is hypogonadotropic hypogonadism, that is, failure of the hypothalamus to produce adequate quantities of gonadotropin-releasing hormone (GnRH). This condition may result from hypothalamic dysfunction, which can occur in Prader-Willi syndrome, Kallmann syndrome (genital-olfactory dysplasia), Laurence-Moon-Biedl syndrome (Danish et al., 1980; Walsh et al., 1978), and the CHARGE association (Ragan et al., 1999). Other causes include an associated growth hormone deficiency or neonatal hypoglycemia secondary to congenital hypopituitarism, congenital pituitary aplasia, and midline brain defects, such as agenesis of the corpus callosum and occipital encephalocele.

Primary testicular failure **hypergonadotropic hypogonadism** is another cause of micropenis and may result from rudimentary testes syndrome or gonadal dysgenesis. It also occurs in Robinow syndrome (Lee et al., 1980b). **The test most frequently used to identify this subgroup is the failure of serum testosterone concentration to rise appropriately after stimulation by hCG.** However, in patients with Kallmann syndrome and cryptorchidism, the serum testosterone level may not increase after the administration of hCG. Rarely, a patient with partial androgen insensitivity syndrome has micropenis, but sexual ambiguity is more common. Micropenis may also result from improper timing or delayed onset of gonadotropin stimulation in the fetus (Lee et al., 1980a). These patients have an idiopathic form of micropenis and a normal hypothalamic-pituitary-testicular axis.

The initial evaluation of a child with micropenis should include a thorough medical history, physical examination, and a karyotype at birth. Accurate measurement of the penile length, palpation of the corporal bodies, and evaluation for cryptorchidism are important elements of the physical examination. Concurrent evaluation with a pediatric endocrinologist assists in determining the cause of the micropenis (central or testicular), assessing for other abnormalities, and helping to determine penile growth potential. **Testicular function is assessed by measuring serum testosterone levels before and after hCG stimulation. Primary testicular failure produces an absent response and elevated basal concentrations of LH and follicle-stimulating hormone (FSH).** In some cases, a GnRH stimulation test is also performed. Anterior pituitary screening tests include serial measurements of serum glucose, sodium, and potassium; serum cortisol concentrations; and thyroid function tests. MRI of the head assesses the anatomic integrity of the hypothalamus, anterior pituitary gland, and midline structures of the midbrain.

Before extensive evaluation of the hypothalamic-pituitary-testicular axis, androgen therapy should be administered to determine the end-organ response. In general, intramuscular testosterone enanthate is given for 3 months. Although prolonged treatment may advance skeletal maturation, short courses of treatment do not affect height. Transdermal testosterone also has been used in these patients (Choi et al., 1993). If androgen treatment in a neonate successfully increases the penis so that its size falls within the normal range, the effects at puberty have not been clearly delineated. In a mouse model of hypogonadotropic hypogonadal micropenis, significant prepubertal exposure of the penis to androgens reduced the ultimate growth response to androgens (Husmann and Cain, 1994; McMahon et al., 1995). Bin-Abbas et al. (1999) described eight boys with micropenis treated with androgens at birth and at puberty. The final penile stretched length averaged 10.3 cm and was in the normal range in all cases. Therefore exogenous stimulation at birth and at puberty with testosterone enanthate seems most reasonable (Tietjen et al., 1998) and is recommended until longer-term studies are available.

If the penis does not respond to testosterone, gender reassignment remains a controversial option. Previously, gender reassignment was recommended, but this position has come under criticism because of the implication that biologic factors, such as testosterone-induced male brain imprinting, during the prenatal period may affect gender identity (Diamond and Sigmundson, 1997). The lack of long-term data regarding the risks and benefits of reassigning these patients to a female gender (Calikoglu, 1999; Diamond, 1999) has resulted in a conservative use of this treatment option. Husmann (2004) described 20 adult men born with micropenis who had a suboptimal response to testosterone therapy and were raised as males. At adulthood, 90% had a micropenis and all had a male gender identity; 5 were undergoing psychiatric counseling for fear of rejection, and 8 had not been sexually active.

Several studies demonstrate that although ultimate penile size may be below the normal range, men born with micropenis have male gender identity and most have satisfactory sexual function. Reilly and Woodhouse (1989) described 20 patients with a primary diagnosis of micropenis in infancy. Almost all had received androgen therapy during childhood, but as adults none had a penis within the normal range of size. All of the boys stood to void. Parents of patients in the prepubertal group considered their children to be normal boys with a satisfactory penile appearance but did express concern about penile size and future sexual function. All of the patients in the adult group had a strong male identity, and 9 of the 12 patients were sexually active. In a study of 22 men born with micropenis, Lee and Houk (2004) had similar findings. Wisniewski and Migeon (2002) reported that their patients had a male gender identity but in general were dissatisfied with their genital appearance and function.

Key Points: Micropenis

- Micropenis is a normally formed penis that measures at least 2.5 SD below the mean size in the stretched length for age (<1.9 cm in neonates).
- Buried penis is not synonymous with micropenis because the buried penis is of normal stretched length.
- The most common causes of micropenis include hypogonadotropic hypogonadism and hypergonadotropic hypogonadism.
- Patient evaluation includes karyotype, determination of serum LH and FSH concentrations; measurement of testosterone levels before and after hCG stimulation; serum studies of anterior pituitary function; MRI of the brain to assess hypothalamus, anterior pituitary, and midbrain.
- In adulthood, most men with micropenis have male gender identity and satisfactory sexual function.

Abnormal Penile Orientation

Penile Curvature

Curvature of the penis may occur along the vertical (i.e., ventral or dorsal direction) or horizontal (i.e., lateral direction) plane of the penis. Penile curvature may be congenital or acquired after penile surgery (circumcision, hypospadias repair) or trauma and has consequences related to cosmesis and body image as well as future sexual difficulties. The indications for surgical repair include known associated sexual dysfunction, concurrent penile surgery, and surgeon's discretion regarding the likelihood of future sexual dysfunction with worsening curvature associated with penile growth.

Penile curvature is most commonly in the ventral direction, referred to as *chordee,* and is commonly associated with hypospadias. However, isolated chordee may occur with or without a dorsal hooded prepuce (Fig. 44.11) and is commonly associated with a deficiency of the ventral skin (Cendron and Melin, 1981). Ventral curvature in boys without hypospadias can usually be corrected by degloving of the penis, excision of fibrous tissue that is usually confined to the region superficial to Buck fascia, and development of Byar flaps for penile skin coverage, as necessary. In more severe cases, simple dorsal plication, Nesbit dorsal excision, or corporal rotation may be necessary. Urethral catheterization may be helpful in averting urethral injury during degloving. In the most severe cases the urethra is short and urethral reconstruction must be performed. Intraoperative artificial erection with injectable saline confirms complete chordee correction. Some cases of chordee may be aggravated by a prominent frenulum, resulting in distal penile chordee with ventral glanular deflection. In these cases, the addition of frenulotomy will improve or correct the chordee.

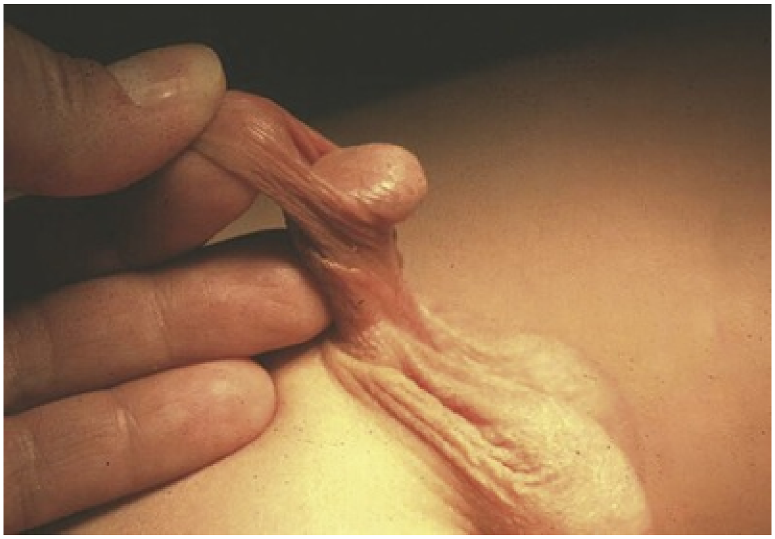

FIG. 44.11 Penile chordee and dorsal hood of foreskin without hypospadias.

Congenital dorsal penile curvature may be an isolated condition with or without asymmetrical penile skin or associated with epispadias and a ventral hood of prepuce. Some individuals may have hypospadias. Surgical repair of this condition without associated urethral anomalies is similar to chordee correction, involving degloving of the penis, excision of fibrous tissue that is usually confined to the region superficial to the Buck fascia, and development of skin flaps for penile skin coverage, as necessary. During correction, the surgeon must be careful to avoid injury to the neurovascular bundles (Baskin, 1999; Baskin et al., 2000). More severe cases involve plication and/or excision of ellipses from the ventral corporal bodies. Intraoperative artificial erection aids in determining the apex of the curvature and confirming chordee correction.

Lateral penile curvature is usually congenital and caused by overgrowth or hypoplasia of one corporal body. However, asymmetrical penile skin excision or postoperative scarring after circumcision or other penile surgery may be a secondary cause. Lateral penile curvature may be unrecognized until later in childhood because the penis is normal when flaccid and only recognized as being curved when erect. Surgical repair of congenital lateral penile curvature involves degloving the penis and performing a plication and/or excision of ellipses from the corporal bodies from the area of maximum curvature to allow straightening of the penis. Secondary lateral penile curvature follows the same principles as for vertical curvature, with degloving of the penis, excision of fibrous tissue that is usually confined to the region superficial to the Buck fascia, and development of skin flaps for penile skin coverage as necessary. Intraoperative artificial erection may be necessary as described earlier.

Penile Torsion

Penile torsion is a rotational deformity of the penile shaft, usually in the counterclockwise direction (i.e., to the left side) (Fig. 44.12). In most cases, penile size is normal and the condition is unrecognized until circumcision is performed or until the foreskin is retracted. Penile torsion may also be associated with hypospadias, chordee, and other abnormalities involving the penile skin shaft, such as dorsal hood deformity without a urethral abnormality. In most cases the median raphe spirals obliquely around the shaft and inserts atypically rather than at the base of the glans in line with the urethral meatus. The cause of penile torsion has not been clearly delineated but may be the result of an anomalous arrangement of penile shaft skin.

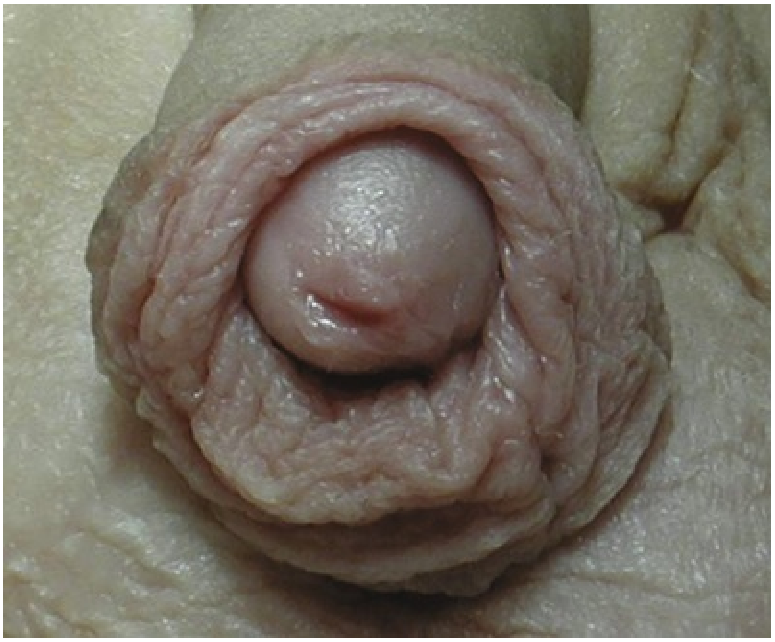

FIG. 44.12 Penile torsion. Patient also has redundant penile skin after a neonatal circumcision.

Most forms of penile torsion are less than 60 degrees. If surgical repair is being considered, neonatal circumcision is discouraged and then performed at the time of penile detorsion. Although the glans may be directed more than 90 degrees from the midline, the orientation of the corporal bodies and the corpus spongiosum at the base of the penis is normal. In mild forms of penile torsion, correction typically involves degloving the penile skin, rotating the glans in the direction opposite to the defect (i.e., clockwise rotation for a counterclockwise abnormality), and suturing the glans to the penile skin, resulting in a glans in a normal configuration (Bar-Yosef et al., 2007). In some instances, the median raphe may take a serpentine course that prevents restoration to a normal position; this is not critical as long as the meatus has a normal configuration. However, in boys with penile torsion of 90 degrees or more, simple shaft skin rearrangement is insufficient. Instead, the base of the penis must be mobilized so that dysgenic bands of fibrous tissue can be identified and incised. If the penis still remains rotated, correction may be accomplished by placing nonabsorbable anchoring sutures at the base of the corpora cavernosa (Elder, 2001; Pomerantz et al., 1978; Slawin et al., 1992), rotating a dorsal dartos flap (Bauer and Kogan, 2009), or mobilizing the urethral plate and urethra (Bhat et al., 2009).

Penile Masses

Penile cysts, congenital or acquired, are the most common penile masses in children. A history of onset, previous surgery, and changes in appearance or size are important in the evaluation of these lesions.

Parameatal Urethral Cyst

The parameatal urethral cyst is a rare anomaly and appears as a small blister in proximity to the urethral meatus (Fig. 44.13A). Shiraki (1975) suggested that these cysts may result from occlusion of paraurethral ducts or in other cases from faulty preputial separation from the glans along the coronal sulcus. The cyst wall may consist of transitional and squamous or columnar epithelium. Treatment is complete excision of the cyst with the patient under anesthesia, with care taken not to cause meatal stenosis (Willis et al., 2011).

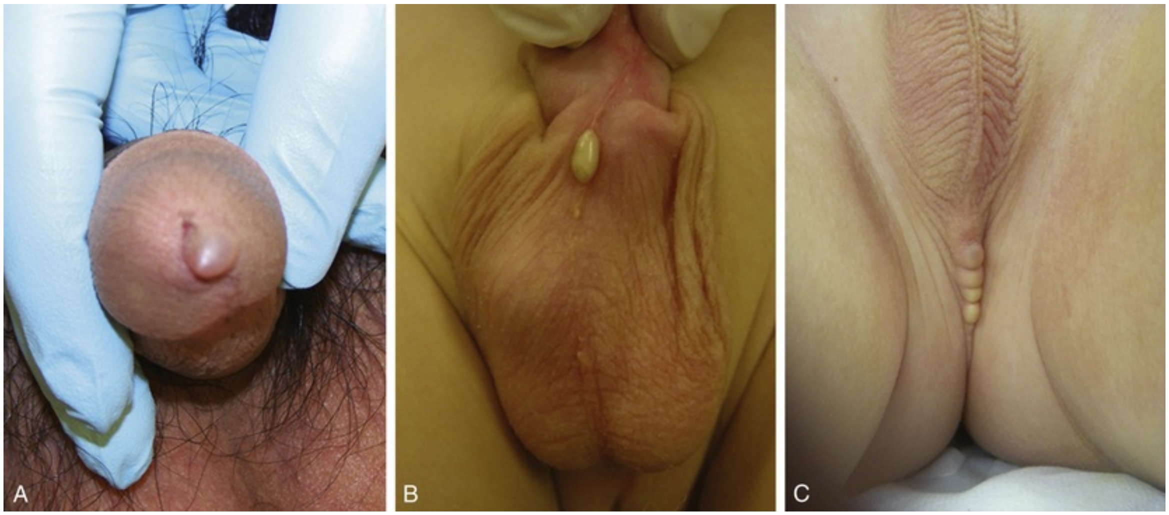

FIG. 44.13 Penile cysts. (A) Parameatal urethral cyst appearing as a small blister. (B) Cyst of the penoscrotal junction raphe. (C) Cysts of the perineal raphe.

Cyst of the Median Raphe

Congenital epidermal cysts tend to form along the median penile raphe on the glans or penile shaft, scrotum, or perineum (Fig. 44.13B and C) (Krauel et al., 2008; Little et al., 1992). These congenital lesions may result from epithelial rests that become buried during the urethral infolding process or represent a monodermal teratoma. Rare cases of cysts enlarging and extending into the pelvis are reported (Huang et al., 1999). Excision with the use of general anesthesia is recommended unless the cysts are small and asymptomatic.

Inclusion Cysts

Epidermal inclusion cysts may form after penile surgery, including circumcision and hypospadias repair, as a result of islands of epithelium within the subcutaneous tissue (Fig. 44.14). Excision of the epidermal inclusion is recommended because these lesions increase in size with time, causing distortion of the skin and possible discomfort during sexual activity.

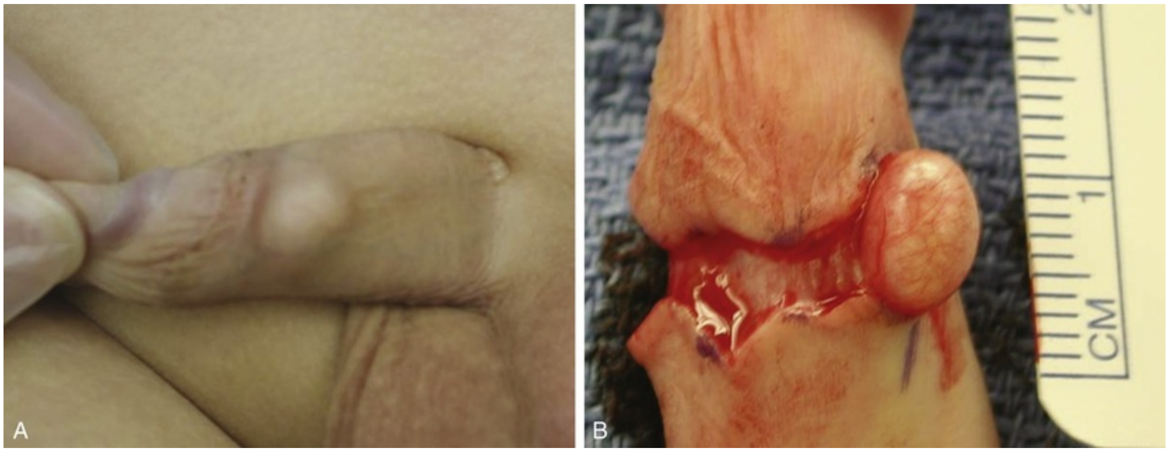

FIG. 44.14 (A) Epidermal inclusion cyst acquired after neonatal circumcision. (B) Cyst exposed and excised intact through an incision of the circumcision scar.

Congenital Penile Nevi

Congenital penile nevi are pigmented lesions that form on the glans and penile shaft (Fig. 44.15). Nevi can be classified based on the location of melanocytes: dermal (involving only the dermis), junctional (involving only the dermal-epidermal junction), and compound (involving the dermis and dermal-epidermal junction). **They tend to be superficial and benign and should be excised** (Papali et al., 2008).

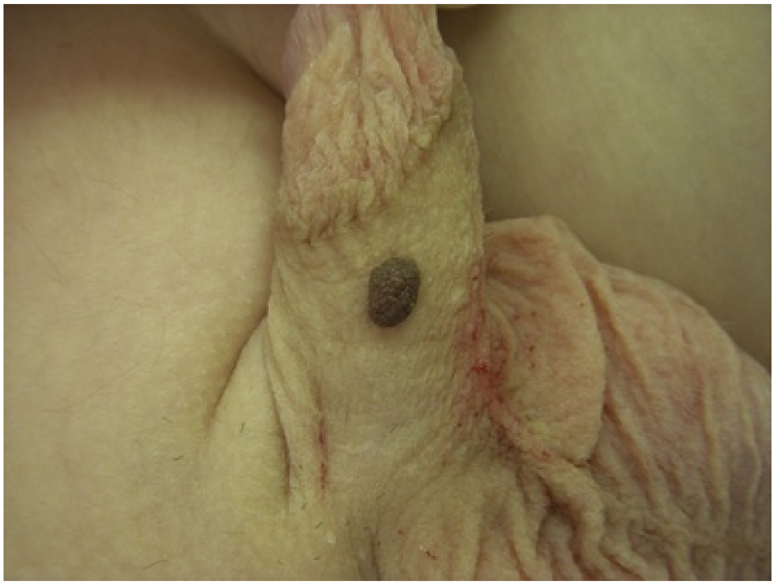

FIG. 44.15 Congenital penile nevus on the penile shaft.

Juvenile Xanthogranuloma

Juvenile xanthogranuloma is an uncommon benign, self-limiting lesion of the penis predominantly seen in infancy or early childhood. These lesions appear as solitary or multiple pigmented (yellow, orange, gold, brown, or red) nodules of rapid onset. They measure 2 to 20 mm in diameter and are well demarcated, firm, and rubbery. These lesions can affect the penis (Bradford and Choudhary, 2009; Hautmann and Bachor, 1993) or scrotum (Dehner, 2003; Goulding and Traylor, 1983), with as many as 20% present at birth. The lesion is often self-limited, and a period of 1 year of expectant monitoring is advised to avoid potentially unnecessary ablative genital surgery.

Accessory Urethral Openings

Congenital Urethral Fistula

Congenital urethral fistula is a condition in which the urethra and meatus are normal and a urethrocutaneous fistula is present, typically located in the coronal or subcoronal position (Fig. 44.16). **This abnormality is usually an isolated deformity** (Tennenbaum and Palmer, 1994) **but may be associated with imperforate anus or ventral chordee** (Ritchey et al., 1994). In a series of 14 such cases, 4 patients had distal hypospadias and 2 had chordee (Caldamone et al., 1999). The cause is unknown but may involve a focal defect in the urethral plate preventing the urethral folds from fusing. The diagnosis is made after circumcision in some cases (Caldamone et al., 1999), raising the possibility that the fistula is instead an iatrogenic injury. Surgical correction may require circumscription of the fistula and closure in multiple layers, similar to a urethrocutaneous fistula after hypospadias repair; or if the glans bridge is thin, the ventral glans can be opened through the distal urethra and then repaired by Thiersch-Duplay tubularization and incision of the urethral plate as needed.

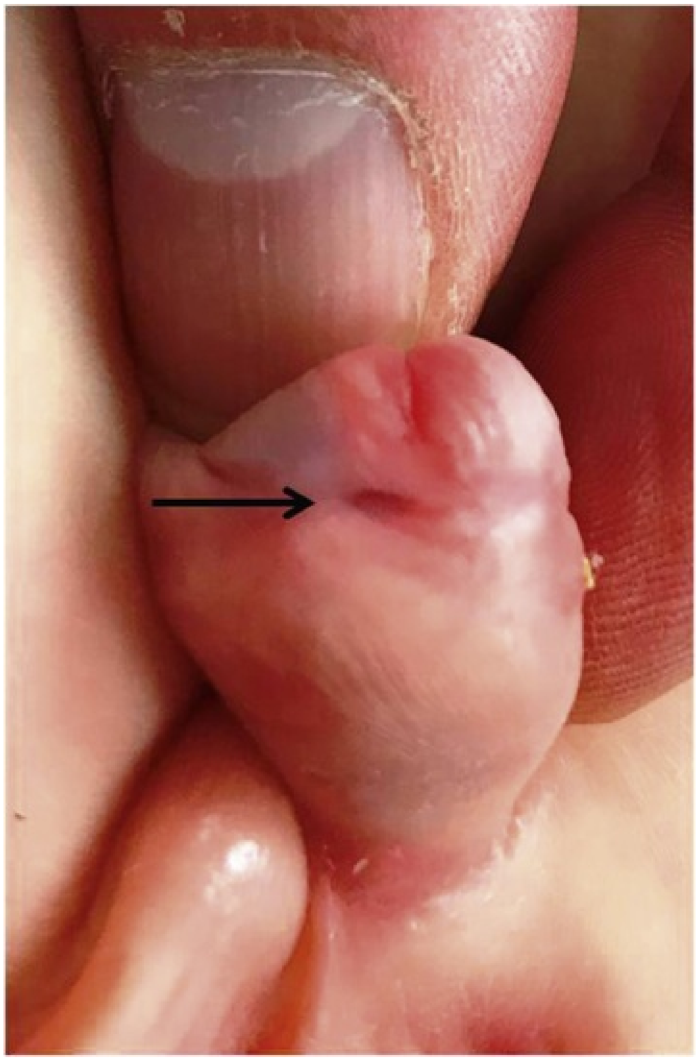

FIG. 44.16 Congenital urethral fistula. The fistula tract *(black arrow)* was noted immediately after circumcision without bleeding noted after the procedure. Urine was noted to come from the fistula and terminal meatus. (Courtesy Moneer Hanna, MD.)

Urethral Duplication

Urethral duplication is a rare congenital anomaly, with roughly 200 reported cases (Salle et al., 2000; Slavov et al., 2007). **The duplication most commonly occurs in the sagittal plane with one urethra located ventrally and the other dorsally** (Fig. 44.17). **Collateral urethral duplication in which urethral duplication occurs in the same horizontal plane is extremely rare** (Ching and Palmer, 2008b). In a series by Salle et al. (2000), sagittal plane duplication accounted for 94% of urethral duplication. Usually the dorsal urethra is considered the accessory urethra with or without a urinary stream, whereas the ventral urethra carries the urine stream and the anatomic landmarks such as the external sphincter and verumontanum. The most commonly used classification of urethral duplication is that of Effman (Fig. 44.18), which describes three types: types I and II distinguish between partial and complete urethral duplication; type III describes urethral duplication as part of bladder duplication (Effman et al., 1976). The embryology of urethral duplication is not well established, with explanations including ischemia (Podesta et al., 1998; Woodhouse and Williams, 1979) and abnormal müllerian duct termination (Das and Brosman, 1977). Effman et al. (1976) suggested that caudal duplication may be related to division of the notochord with subsequent formation of two hindguts, allantoises, and cloacae.

FIG. 44.18 Effman classification.

Associated genitourinary, gastrointestinal, and musculoskeletal anomalies may be present. In the review by Podesta et al. (1998), six of seven patients with urethral duplication had other associated anomalies, the most common vesicoureteral reflux. Other anomalies included renal agenesis, bilateral cryptorchidism, sacral agenesis, imperforate anus, radial hypoplasia, and tracheoesophageal fistula. There appears to be an association with other midline defects such as duplicated bladder, duplicated colon, imperforate anus and anorectal agenesis, bifid glans, thoracic hemivertebrae, and partial sacral agenesis (Fenster et al., 1980; Kennedy et al., 1988; Salle et al., 2000; Woodhouse and Williams, 1979).

The most common presentation of urethral duplication is a double meatus and double urinary stream (Kennedy et al., 1988; Salle et al., 2000; Urakami et al., 1999). Incontinence and recurrent UTIs are other common presentations. Less common conditions include penile chordee and urinary obstruction secondary to a mucosal flap at the urethral bifurcation acting as an occluding valve during voiding (Das and Brosman, 1977; Effman et al., 1976; Salle et al., 2000). The presence of incontinence is dependent on the site of origin of the accessory urethra; the more proximal the site of urethral duplication, the higher the incidence and the greater the degree of incontinence (Farrell and Sparnon, 1987).

Patient evaluation should include a voiding cystourethrogram, retrograde urethrogram, and direct visualization of the anatomy during cystourethroscopy. Evaluation of the other associated anomalies should also be undertaken. Treatment of urethral duplication is usually reserved for the symptomatic child (Urakami et al., 1999). Cosmesis alone, however, has been advocated by some as a valid indication for intervention (Middleton and Melzer, 1992). The accessory urethra should not be used as the primary urethra secondary to being hypoplastic with the risk of inadequate urine flow (Salle et al., 2000). Surgical repair includes complete accessory tract excision, electrofulguration or injection of sclerosing agents into the accessory tract, septotomy if the septum between the two urethras is thin, and urethrourethrostomy of the accessory tract into the functional urethra. Management is dependent on the anatomy of the urethral duplication (Farrell and Sparnon, 1987; Podesta et al., 1998).

Genital Lymphedema

Lymphedema of the genitalia, congenital or acquired, is a disfiguring disorder characterized by impaired lymphatic drainage that causes progressive penile or scrotal swelling. Congenital lymphedema may be sporadic (85%) or inherited (15%) and can be expressed at various ages (McDougal, 2003). Milroy disease is an autosomal dominant inherited trait, whereas Meige disease is probably autosomal dominant with variable penetrance and occurs in the first or second decade (Wheeler et al., 1981). Anogenital granulomatomosis is a rare condition that has a delayed presentation and is associated with Crohn's disease. Azathioprine treatment resulted in complete or partial resolution of the edema in 60% of patients in one study (Alexakis et al., 2017). If the genital lymphedema occurs at puberty and is sporadic, it is termed *lymphedema praecox.* Approximately 80% of patients with congenital lymphedema demonstrate onset of the disease at puberty (McDougal, 2003). The lymphedema may involve the penis, the scrotum, or both. Congenital lymphedema has been associated with several syndromes, including Turner, Noonan, Klinefelter, and intestinal lymphangiectasia syndromes. Lower extremity involvement may also occur.

Initial management involves observation, but surgical therapy is necessary if the lymphedema remains significant or progresses. The goal of surgical treatment is to remove all involved tissue. On the penile shaft, the penis is degloved and all tissue between the Buck fascia and the skin as well as redundant penile skin must be excised. If the patient is uncircumcised, the prepuce may be unfurled to provide coverage of the penile shaft (Shenoy et al., 2001). If the scrotum is involved, the scrotal skin must be excised, with the exception of the posterior skin, and the spermatic cords and testes should be preserved (Ross et al., 1998). The penis may be covered with local skin flaps, and the scrotal contents may be covered with uninvolved posterior skin flaps (Bolt et al., 1998; Ross et al., 1998). Split-thickness skin flaps may be needed to cover the penis and scrotum if inadequate healthy skin is available (McDougal, 2003). Parents should be counseled that lymphedema in adjacent areas may recur after definitive surgical therapy.

Priapism

Priapism is fortunately an uncommon condition in the general pediatric population. It is defined as a prolonged, commonly painful penile erection sustained for longer than 4 hours with the absence of physical and psychological stimulation. Tumescence is usually restricted to the corpora cavernosa (Montague et al., 2003), and in some cases the corpus spongiosum involves the glans. Priapism can be categorized into three types:

1. Ischemic (veno-occlusive, low-flow) priapism is characterized by little or no cavernous blood flow, and cavernous blood gases are hypoxic, hypercapnic, and acidotic. The corpora are rigid and tender to palpation.
2. Nonischemic (arterial, high-flow) priapism is caused by unregulated cavernous arterial inflow. Typically, the penis is neither fully rigid nor painful. There is often a history of antecedent trauma resulting in a cavernous artery or corpora cavernosa fistula.
3. Stuttering (intermittent) priapism is a recurrent form of ischemic priapism with painful erections of shorter duration and intervening periods of detumescence.

The evaluation and management of priapism is similar to that in adults with accommodations made for children as outlined in the guidelines offered by the American Urological Association (Montague et al., 2003) **and European Association of Urology** (Salonia et al., 2014). **Low-flow priapism is most commonly secondary to homozygous sickle cell disease,** which is characterized by predominance of sickle hemoglobin (HbS). Other causes include leukemia, other hemoglobinopathies, and local malignancy (Dewan et al., 1989; Friedman, 1998). Sickle cell–induced priapism occurs in 2% to 29% of males with the disease (Hamre et al., 1991; Mantadakis et al., 1999; Miller et al., 1995; Tarry et al., 1987). The priapism associated with sickle cell disease is generally related to sickling of red blood cells within the sinusoids of the corpora cavernosa during normal erection, resulting in venous stasis. The resulting decreased pH and local oxygen tension potentiates further stasis and sickling (Bruno et al., 2001). Priapism typically occurs during sleep, when mild hypoventilatory acidosis depresses oxygen tension and pH in the corpora or as a result of oxyhemoglobin desaturation (Roizenblatt et al., 2012). The pain that is experienced is a sign of ischemia.

Transient prolonged erections lasting less than 2 hours, stuttering priapism, is more common than prolonged erections in the patient with sickle cell disease. Pseudoephedrine, an oral α-adrenergic agent, given at bedtime promotes muscle contraction within the erectile tissue. If this treatment is unsuccessful, other agents can be used, including an oral β agonist. Recently, preliminary findings have suggested that the use of continuous, long-term oral phosphodiesterase type 5 (PDE5) inhibitor therapy may prevent recurrent priapism based on the hypothesis that PDE5 dysregulation may be involved in priapism (Burnett, 2008; Burnett et al., 2006).

The initial treatment of low-flow priapism resulting from sickle cell disease is conservative, with hydration, oxygenation, alkalization, analgesia, and exchange transfusion aimed at reducing HbS concentration (Hamre et al., 1991; Miller et al, 1995; Seeler, 1973). **Evacuation of blood and irrigation of the corpora cavernosa along with intracavernous injections of α-adrenergic sympathomimetic agents, such as phenylephrine or epinephrine solution, can be a concurrent therapy** (Montague et al., 2003). Surgical shunt procedures to facilitate corporal drainage are indicated in the absence of response to medical therapy (Chakrabarty et al., 1996; Miller et al., 1995; Tarry et al., 1987). Surgical shunting bypasses the veno-occlusive mechanism of the corpora cavernosa and thereby enhances blood drainage. Shunt procedures include distal cavernoglanular shunt (Winter, Ebbehoj, and Al-Ghorab shunts) (Ebbehoj, 1974; Ercole et al., 1981; Winter, 1976), proximal cavernospongiosal shunt (Quackels and Sacher shunts) (Quackels, 1964; Sacher et al., 1972), or saphenous vein anastomosis to one of the corpora cavernosa (Grayhack shunt; Grayhack et al., 1964). Parents should be educated on the potential side effects from intervention, including cavernosal fibrosis and erectile dysfunction.

High-flow priapism is usually a result of perineal trauma, such as a straddle injury. Other causes include Fabry disease and sickle cell anemia (Callewaert et al., 1998; Ramos et al., 1995; Volkmer et al., 2001). Corporal irrigation is diagnostic and therapeutic. Typically, the aspirated blood is bright red and the aspirate is similar to arterial blood on blood gas analysis. Color Doppler ultrasonography (CDUS) often shows the fistula. The initial management is observation (Montague et al., 2003) because spontaneous resolution may occur. Superselective embolization of cavernous and penile arteries (Callewaert et al., 1998; Kuefer et al., 2005; Montague et al., 2003; Volkmer et al., 2001) is the next line of therapy.

A fourth type of priapism is a spontaneously resolving form observed in neonates (Walker and Casale, 1997). Causes may include idiopathic factors, birth trauma, and polycythemia. No intervention is necessary because the priapism usually resolves in 2 to 6 days without adverse results.

Key Points: Priapism

- Priapism can be ischemic (veno-occlusive, low flow), nonischemic (arterial, high flow), and stuttering (intermittent).

- The most common cause for priapism in children is sickle cell disease.
- The initial treatment of low-flow priapism resulting from sickle cell disease is conservative with hydration, oxygenation, alkalinization, and transfusion. Evacuation of blood and irrigation of the corpora cavernosa along with intracavernous injection of α-adrenergic sympathomimetic agents can be done concurrently or after failure of conservative measures.
- High-flow priapism is usually due to perineal trauma, such as a straddle injury. Angiographic embolization should be performed if spontaneous resolution fails to occur.
- Transient but potentially prolonged periods (less than 2 hours) of erection or stuttering priapism can be treated with pseudoephedrine given at bedtime.

Penoscrotal Transposition (Scrotal Engulfment)

Penoscrotal transposition may be partial or complete (Fig. 44.19), with its less severe forms having been termed *doughnut scrotum*, *prepenile scrotum*, and *shawl scrotum*. The embryologic cause may result from incomplete or failed inferomedial migration of the labioscrotal swellings. The use of 2D and 3D ultrasound during gestation has been successful in identifying the condition in utero (Wang et al., 2011). **Frequently, it occurs in conjunction with perineal, scrotal, or penoscrotal hypospadias with chordee** (Pinke et al., 2001). Penoscrotal transposition has also been associated with caudal regression (Lage et al., 1987), sex chromosome abnormalities (Yamaguchi et al., 1989), and Aarskog-Scott syndrome (Shinkawa et al., 1983). As many as 75% of patients with complete penoscrotal transposition and a normal scrotum have a significant urinary tract abnormality, including renal agenesis and dysplasia (MacKenzie et al., 1994; Parida et al., 1995), and other nongenitourinary anomalies have been reported. These patients should be evaluated with renal ultrasonography and voiding cystourethrography.

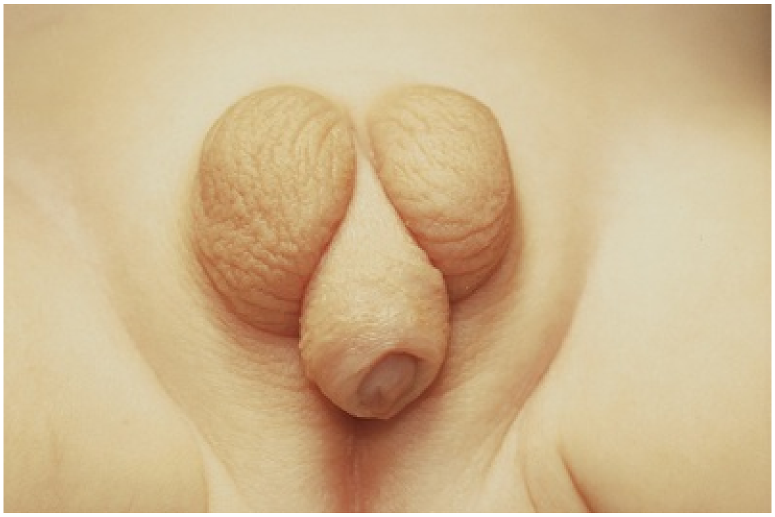

FIG. 44.19 Penoscrotal transposition.

Surgical repair is usually performed during hypospadias or other penile repair. Several scrotoplasty techniques have been described (Ehrlich and Scardino, 1982; Glenn and Anderson, 1973; Levy et al., 1997) with the goal of freeing the penis from the scrotum, developing skin flaps, relocating the scrotum to a dependent position, and moving the penis superiorly. Scrotoplasty is performed by circumscribing the superior aspects of each half of the vertical aspect of the scrotum and extending these incisions laterally to include at least half of the scrotum (Fig. 44.20). The medial aspects of the incision are joined on the ventral aspect of the penis, and the incision is carried down the midline along the median raphe. The injection of a solution of lidocaine with epinephrine into the subcutaneous tissue can be used to develop tissue planes and also help to diminish bleeding. Care must be taken not injure the tunica vaginalis and spermatic cord during deeper dissection. The scrotal wings are rotated medially under the penis and sutured together in the midline in an everted manner. Although in most cases there is no deficiency of the ventral penile shaft skin, in more severe cases of penoscrotal transposition dorsal interposition flaps may be necessary, allowing caudal advancement of the skin of the abdominal wall (Pinke et al., 2001).

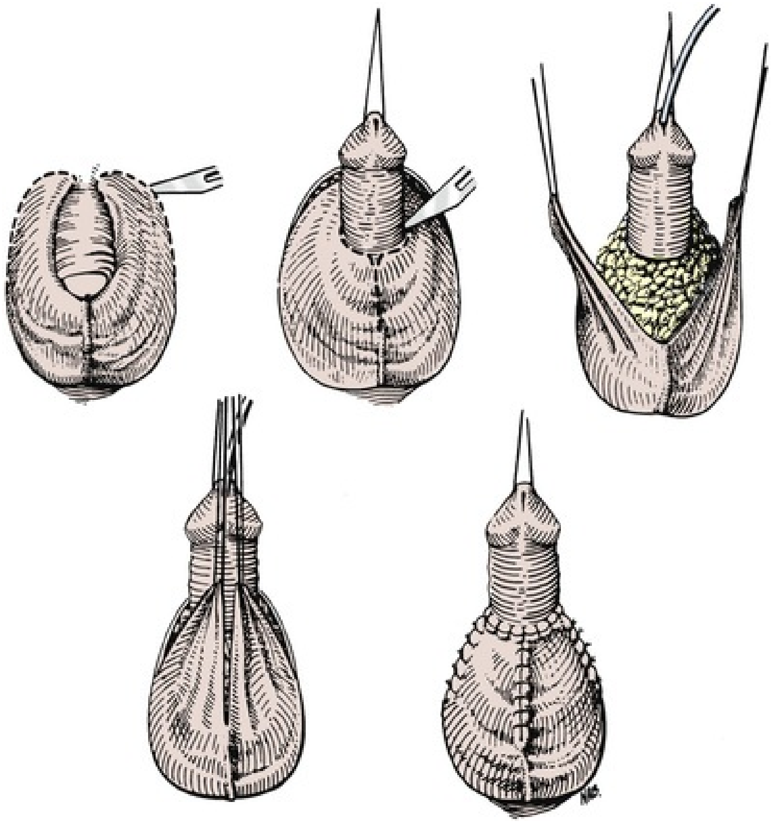

FIG. 44.20 Repair of penoscrotal transposition using rotation flaps of the scrotum (see discussion in text).

An alternative technique is to identify the correct position for the penis and make a buttonhole by excising a plug of epidermis, dermis, and suprapubic fat (Kolligian et al., 2000). The penis is then degloved, and the penile shaft is brought through the buttonhole. The penile shaft skin remains behind, is split down the ventrum, and is mobilized superiorly to the penile shaft. A window of the dartos pedicle is made, and the penile shaft is brought through this window. The degloved penis is then resurfaced with shaft skin (Fig. 44.21).

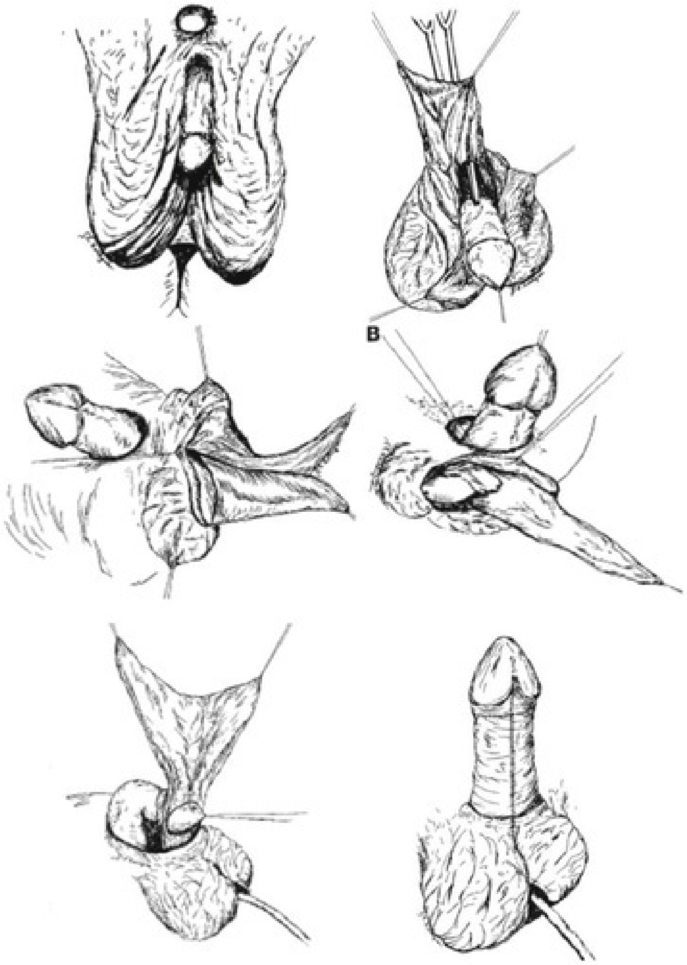

FIG. 44.21 Repair of penoscrotal transposition by relocating the position of the penis (see discussion in text).

Scrotal Anomalies

Bifid Scrotum

Bifid scrotum refers to the deformity in which the labioscrotal folds are completely separated and without a median raphe. This anomaly is most often associated with proximal hypospadias. Surgical repair is usually performed during hypospadias repair. The technique is similar to that used for repair of penoscrotal transposition. An alternative is the use of single or multiple Z-plasty procedures to correct the defect (Mokhless et al., 2011; Fig. 44.22).

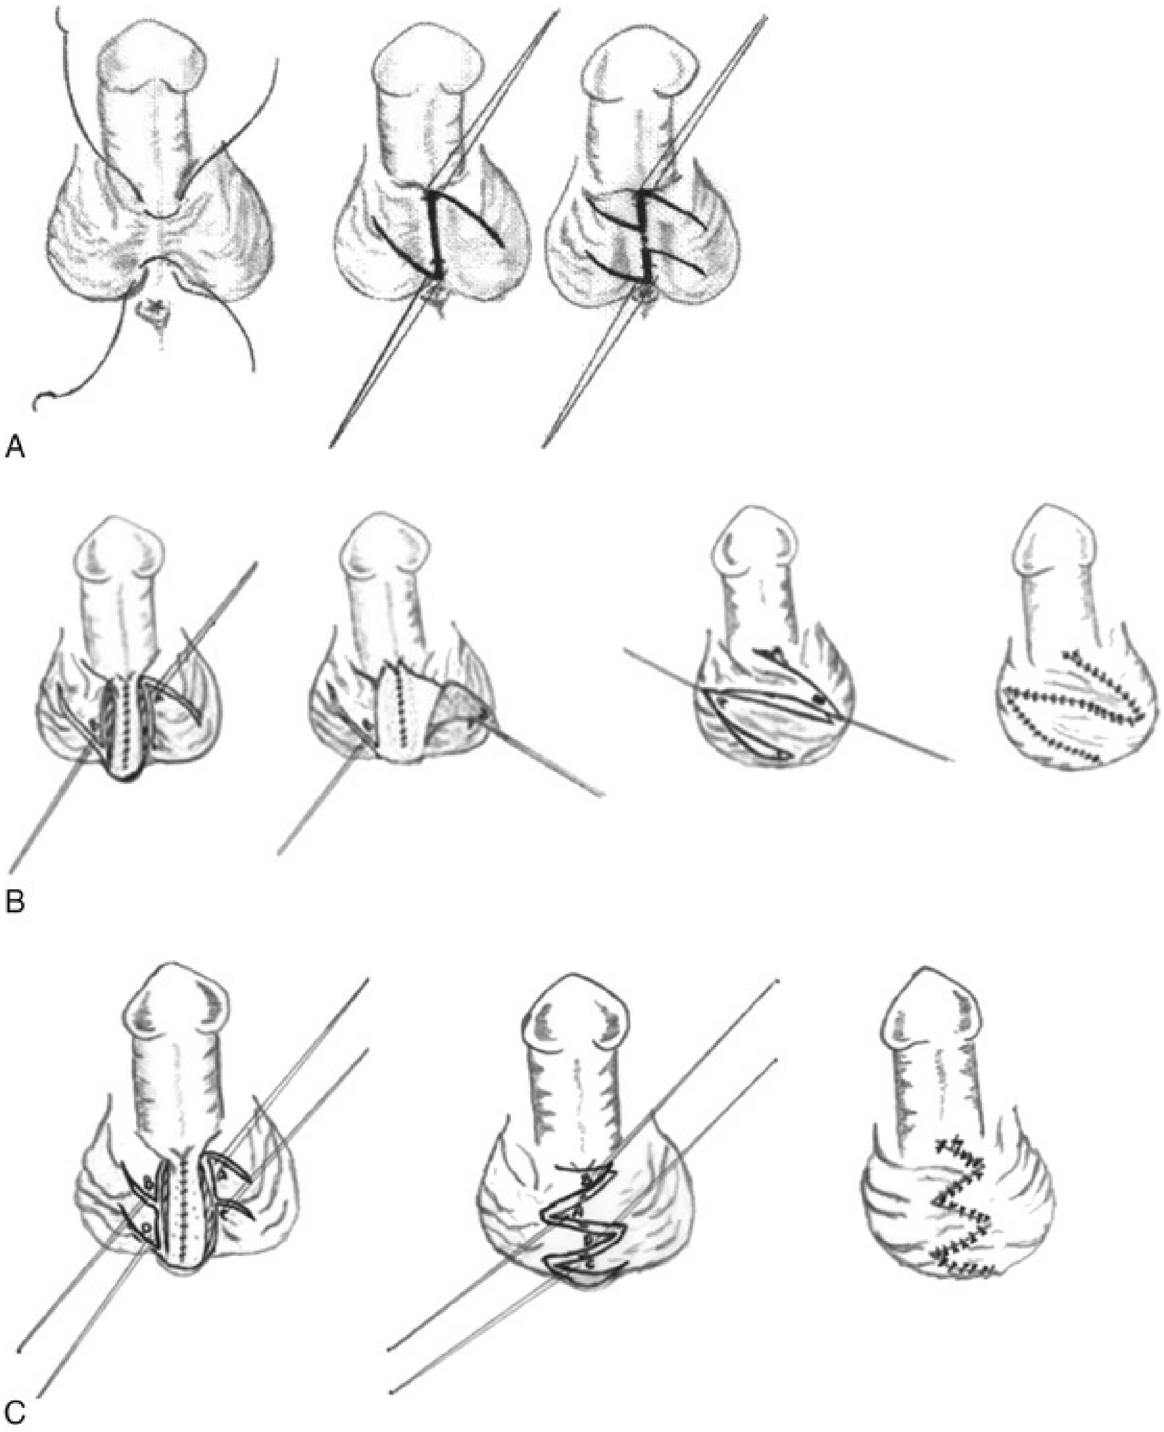

FIG. 44.22 Use of Z-plasties to correct the bifid scrotum. (A) The placement of initial stay sutures *(left)* and drawing lines of simple *(middle)* or multiple Zs *(right)*. The development of the flaps and their rearrangement are seen for a simple Z-plasty (B) and multiple Zs (C). (From Mokhless I, Youssif M, Eltayeb M, et al.: Z-plasty for sculpturing of the bifid scrotum in severe hypospadias associated with penoscrotal transposition. *J Pediatr Urol* 7:305–309, 2011.)

Ectopic Scrotum

Ectopic scrotum (Fig. 44.23), the anomalous position of one hemiscrotum, is a rare condition. The location can be suprainguinal (most common), infrainguinal, or perineal (Elder and Jeffs, 1982; Lamm and Kaplan, 1977). This anomaly has been associated with cryptorchidism, inguinal hernia, and bladder exstrophy as well as with the popliteal pterygium syndrome (Cunningham et al., 1989). In one review, 70% of boys with a suprainguinal ectopic scrotum exhibited ipsilateral upper urinary tract anomalies, including renal agenesis, renal dysplasia, and ectopic ureter (Elder and Jeffs, 1982). Another study indicated that an associated perineal lipoma was found in 83% of these children; 68% of those with a lipoma had no associated anomalies, whereas 100% of those without a lipoma had associated genital or renal malformations (Sule et al., 1994). **Patients with an ectopic scrotum should undergo upper urinary tract imaging with ultrasonography.** Because the embryology of the gubernaculum and of the scrotum are intimately related chronologically and anatomically, the ectopic scrotum may result from a defect in gubernacular formation that prevents migration of the labioscrotal swellings (Hoar et al., 1998). Scrotoplasty and orchiopexy may be performed at 6 to 12 months of age or earlier if other surgical procedures are necessary for associated anomalies.

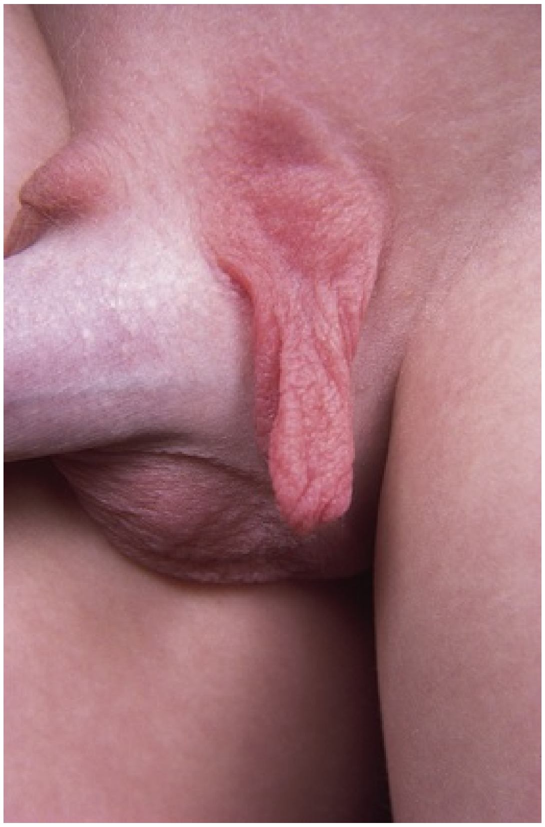

FIG. 44.23 Ectopic scrotum.

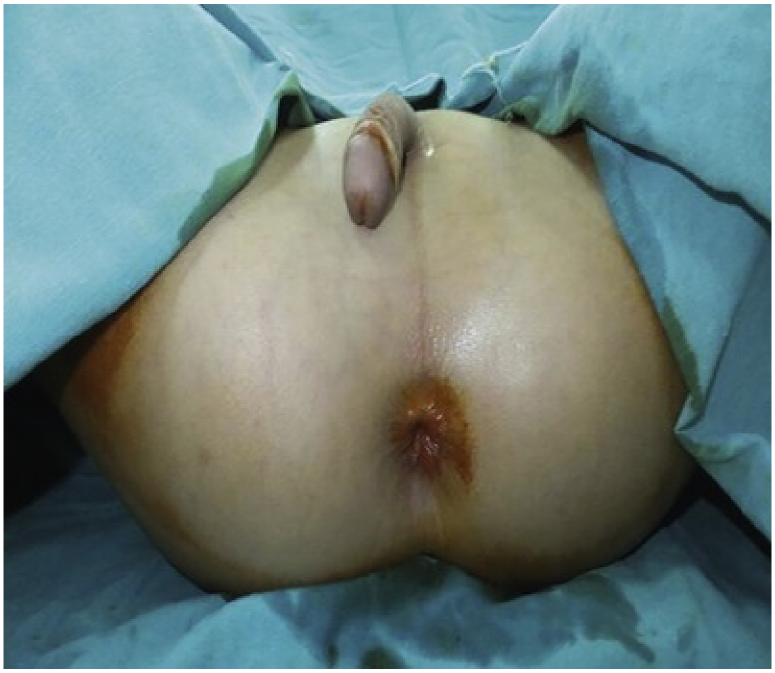
Scrotal Hypoplasia

Scrotal hypoplasia, the underdevelopment of one or both sides of the scrotum, **occurs most commonly in boys with an undescended testis** and in infants with genital ambiguity. The deformity may result from lack of gubernacular swelling of the labioscrotal folds.

Scrotal Agenesis

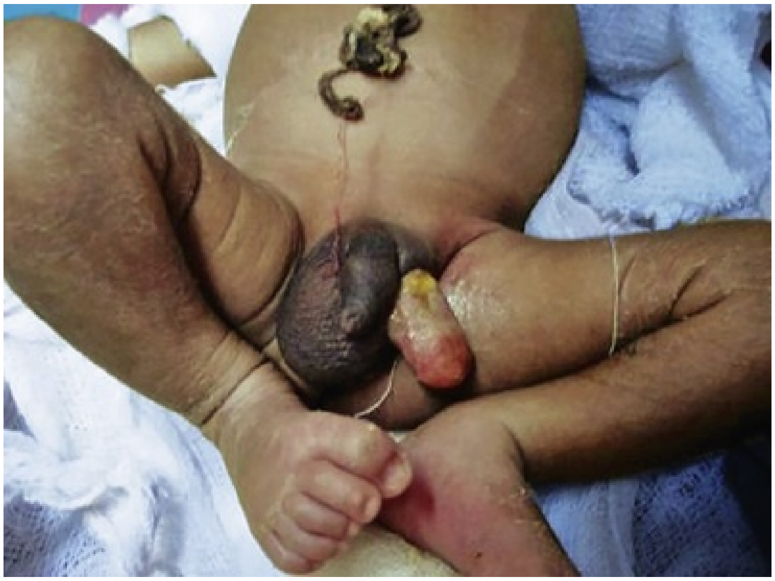
The absence of the scrotum or hemiscrotum is rare (eFig. 44.24). All seven of the reported cases of scrotal agenesis had XY karyotype and bilateral undescended testes; the presence of the median raphe; and other anomalies such as cognitive impairment, bilateral nystagmus, cleft palate, and syndactyly (Silay et al., 2013). Two cases of hemiscrotal agenesis have been reported. In one case, multiple anomalies were found; in the second case an isolated hemiscrotal agenesis was reported. In both cases the penis and contralateral hemiscrotum and contents were normal. In addition, the testes on the affected side were in what would have been the normal location (Flum et al., 2012; Yilmaz et al., 2013).



EFIG. 44.24 Congenital agenesis of the scrotum. (From Silay MS, Yesil G, Yildiz K, et al.: Congenital agenesis of scrotum and labia majora in siblings. *Urology* 81:421–423, 2013.)

Scrotoschisis

Meconium peritonitis may occasionally cause genital manifestations, including meconium hydrocele (Ring et al., 1989) and congenital rupture of the scrotum, termed *scrotoschisis* (Chun and St-Vil, 1997; Gongaware et al., 1991; Kojori and Demaria, 2007; Premkumar et al., 2009; Salle et al., 1992). This can result in one or both testes being extruded from the scrotal sac. When scrotoschisis is detected, the clinician should suspect meconium peritonitis and proceed with the appropriate evaluation. Treatment involves scrotal exploration with orchiopexy and primary closure of the scrotal wall defect (eFig. 44.25).



EFIG. 44.25 Congenital scrotoschisis and exposed testis. (From Shukla RM, Mandal KC, Roy D, et al.: Scrotoschisis: an extremely rare congenital anomaly. *J Indian Assoc Pediatr Surg* 17:176–177, 2012.)

Vascular Lesions of the Genitalia

Vascular lesions of the genitalia are uncommon without a consensus on classification, cause, and treatment. These deformities include hemangiomas and vascular malformations. **Hemangiomas are on the skin**, are often congenital, and may show significant growth in the postnatal period followed by slow involution. **Vascular malformations are present at birth in the subcutaneous tissues** and tend to persist or to enlarge, which can occur secondary to trauma, sepsis, or hormonal changes (Ramos et al., 1999). **Vascular malformations can be subdivided into either slow-flow (capillary, lymphatic, venous) or fast-flow (arterial, arteriovenous) types.**

Congenital Hemangiomas

Congenital hemangiomas are common and affect the genitalia in approximately 1% of all hemangiomas (Alter et al., 1993). The origin of these lesions and the mechanisms regulating their growth and involution are controversial (Ritter et al., 2007). **Strawberry hemangiomas are the most common type and result from proliferation of immature capillary vessels.** These are also categorized as cutaneous hemangiomas because they occur on the skin. Although the lesions may undergo a period of rapid growth lasting 3 to 6 months, gradual involution is common, and most lesions require no treatment (Casale and Menashe, 1989; Girard et al., 2006). If ulceration develops, intervention is necessary to prevent complications from bleeding. The most popular form of therapy is short-term oral corticosteroid therapy or propranolol (Tran et al., 2016).

Treatment with laser therapy allows selective photothermolysis and destruction of superficial blood vessels (Kennedy et al., 1993; Ward et al., 1998). In some cases, surgical excision is necessary.

Subcutaneous Hemangiomas

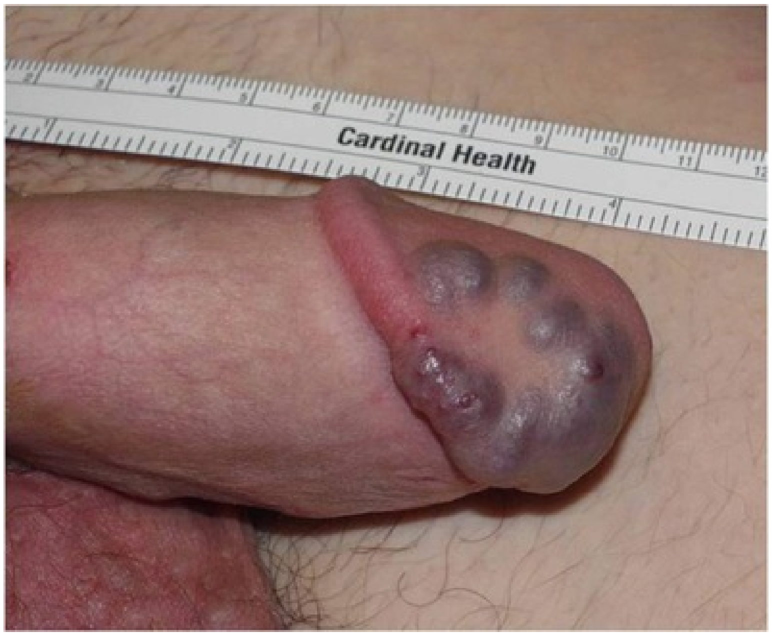
Subcutaneous hemangiomas, also referred to as *cavernous hemangiomas*, are much less common than the cutaneous variety (Ferrer and McKenna, 1995; Sule et al., 1993) and are probably more appropriately classified as a vascular malformation. They may be detected at birth or later in life. In contrast to cutaneous hemangiomas, which tend to involute, cavernous hemangiomas tend to enlarge gradually and should be treated with care. Physical examination reveals a “bag of worms” sensation similar to that of a varicocele, although the lesions tend to be firm and do not decompress when the patient is recumbent. Ultrasonography with color Doppler imaging, computed tomography (CT), or MRI is recommended to delineate the size of the hemangioma (Aizenstein et al., 1996) because examination does not disclose the extent of the lesion. Definitive treatment by en bloc resection is advised, and preoperative angioembolization may reduce the size of the mass and the risk of bleeding.

Klippel-Trénaunay-Weber Syndrome

Klippel-Trénaunay-Weber syndrome is a triad of cutaneous vascular malformation, most commonly nevus flammeus, in combination with soft tissue and bone hypertrophy. The anomaly manifests at birth, usually involving a lower extremity, but it may also involve the trunk or face. These vascular lesions have a propensity to bleed. In a review of 214 patients from a single institution, Husmann et al. (2005) found that 30% had genitourinary cutaneous or visceral involvement. Of the 48 (22%) who had cutaneous genital involvement, 29% developed intractable bleeding. Excision of the hemangiomas was associated with significant blood loss.

Vascular Malformations

The penis may also be affected by vascular malformations (Fig. 44.26). These lesions are congenital but are usually not diagnosed until the teenage years or young adulthood. The lesions are characterized as a faint blue patch or a soft blue mass. Careful excision is effective (Kaufman et al., 2010), but if the lesion affects the glans penis, the neodymium:yttrium-aluminum-garnet laser may yield a better result (Ramos et al., 1999).



Cardinal Health

FIG. 44.26 Venous malformation of the glans.

Hernia and Hydroceles

Embryology

Patients with inguinoscrotal pathology, namely inguinal hernias and hydroceles, are commonly referred to pediatric urologists for diagnostic confirmation and management. **The processus vaginalis forms during the third month of gestation as the peritoneum bulges into the inguinal canal just before the onset of testicular descent.** On completion of testicular descent, the processus vaginalis obliterates and the portion adjacent to the testes becomes the tunica vaginalis. Obliteration of the processus vaginalis continues postnatally, and its failure to obliterate accounts for nearly all inguinoscrotal abnormalities seen in infancy and childhood. In an autopsy series, Mitchell found closure of the processus vaginalis in 18% of full-term infants at birth (Mitchell, 1939). Among 1965 children undergoing unilateral inguinal hernia repair, Rowe identified a patent contralateral processus vaginalis in 63% of patients younger than 2 months and about 40% of those 1 to 2 years of age, with similar frequency up until age 16 years (Rowe et al., 1969). The incidence of incidental patency observed in older children and adults at autopsy or laparoscopy is about 20% (Ajmani and Ajmani, 1983; van Wessem et al., 2003).

Definitions (Fig. 44.27)

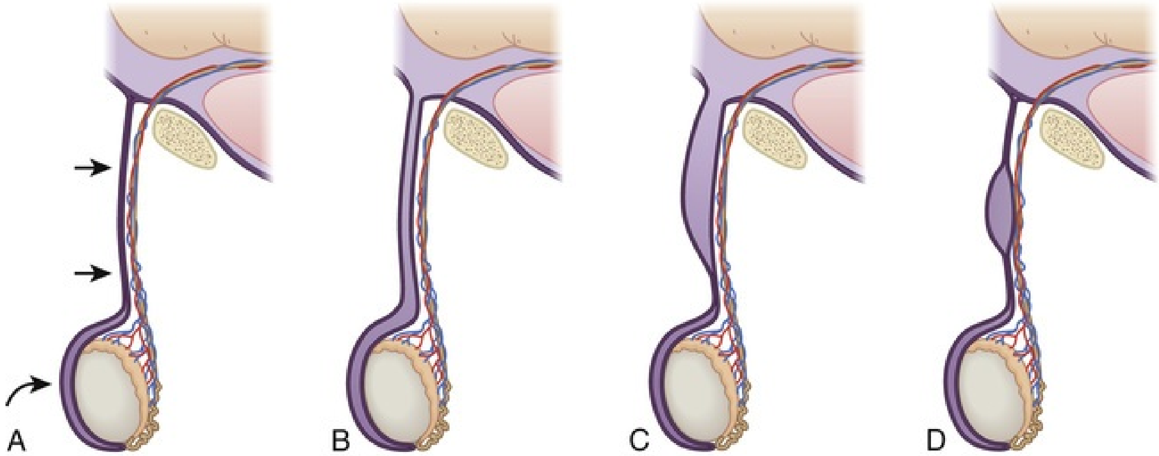


FIG. 44.27 Anatomy of the processus vaginalis in hydrocele. (A) Normal closure of the processus vaginalis; *straight arrows* indicate the funicular process; *curved arrow* is the tunica vaginalis. (B) Communicating hydrocele

with complete patency of the processus vaginalis. (C) Funicular hydrocele with distal closure of the processus vaginalis; communication with the peritoneal cavity may also result in hernia. (D) Encysted hydrocele of the spermatic cord. (From Martin LC, Share JC, Peters C, et al.: Hydrocele of the spermatic cord: embryology and ultrasonographic appearance. *Pediatr Radiol* 26:528–530, 1996.)

Indirect inguinal hernia: a widely patent processus vaginalis extending beyond the internal inguinal ring containing abdominal contents (peritoneal fluid, bowel, omentum, gonads), which may pass into the inguinal canal, labia, or scrotum

Communicating hydrocele: a patent processus vaginalis extending beyond the internal inguinal ring containing peritoneal fluid alone, which extends to the testis, with fluid within the tunica vaginalis

Hydrocele of the spermatic cord: fluid contained within a segment of patent processus vaginalis with obliterated processus distally and proximally

Scrotal hydrocele: fluid contained within the tunica vaginalis surrounding the testis without communication proximally

Abdominoscrotal hydrocele: a large scrotal hydrocele that extends proximally across the internal inguinal ring into the abdomen without communication with the peritoneum

Epidemiology and Pathogenesis

Inguinal Hernia and Communicating Hydrocele

Inguinal hernias develop in 1% to 5% of children. The incidence is 5 to 10 times more common in boys and significantly more common among premature infants (13% of babies born before 32 weeks and nearly 30% of babies weighing less than 1 kg). The propensity for the right side (3:1) is attributed to the later descent of the right testicle (Brandt, 2008; Burgmeier et al., 2015; Jones et al., 1998). **Female gender, prematurity, age younger than 1 year, and history of cryptorchidism are risk factors for bilaterality** (Brandt, 2008; Ein et al., 2006). One study suggests a protective effect of breastfeeding against the development of inguinal hernias (Pisacane et al., 1995). Whereas hernias may occur at any time during childhood, the **average age at presentation is 3 to 4 years,** with nearly one-third of cases manifesting before age 6 months (Kapur et al., 1998). Concomitant hydroceles are frequently seen; 19% of 6361 cases were found by Ein et al. (2006) (70% scrotal, 26% cord, and 4% both).

The majority of new hydroceles occurring after birth and before puberty are associated with a patent processus vaginalis (i.e., communicating hydrocele). In an observational study, 59% of 302 newly identified hydroceles in patients 1 to 18 (mean 4.4) years of age were clinically communicating (clear history of fluctuation), and 6% were spermatic cord hydroceles (Christensen et al., 2006). Seventy (65%) of the apparently noncommunicating and 5 (29%) of the cord hydroceles were followed, and spontaneous resolution was noted in 39 and 3, respectively. Among boys undergoing hydrocele repair, complete obliteration of the processus vaginalis was noted in 0 to 22% of cases (Barthold and Redman, 1996; Elder, 1992; Han and Kang, 2002).

Noncommunicating Hydroceles

Hydroceles that spontaneously resolve during infancy or appear during or after puberty are more commonly noncommunicating. These form from delayed fluid absorption or abnormal fluid dynamics within the tunica vaginalis or less commonly in response to tumor, trauma, or inflammation. Simple scrotal hydroceles occur in at least 5% of male neonates (Osifo and Osaigbovo, 2008), are typically bilateral, and resolve with fluid reabsorption.

Genetics and Associated Conditions

A genetic predisposition to developing inguinal hernias exists, and potential genome sites have been identified. Among probands, there is a 28% risk in other family members and a higher relative risk in first-degree relatives (6.9), particularly female siblings (17.8) of affected girls (Gong et al., 1994; Jones et al., 1998). Genetic transmission appears to be autosomal dominant with reduced penetrance. Zhang has implicated DNA sequence variants (DSVs) within T-box transcription factor 1 (TBX1) and TBX2 as rare causes (Zhang et al., 2014a, 2014b). Sezer identified polymorphisms of the collagen type I α1 (COL1A1). The Sp1 binding site was associated with a higher risk of developing inguinal hernias (Sezer et al., 2014).

Hernias are associated with other diseases and anomalies. These include bladder exstrophy, epididymal anomalies, connective tissue disorders, cystic fibrosis, and posterior urethral valves. Inguinal hernia is also a component of more than 200 syndromes, many of which have known specific genetic alterations (Winter-Baraitser Dysmorphology Database, www.lmdatabases.com).

Other genital anomalies such as polyorchidism, transverse testicular ectopia with or without persistent müllerian ducts, and splenogonadal fusion may be seen at the time of hernia repair. Abnormal epididymal-testicular attachment correlates with degree of closure of the processus vaginalis (Barthold and Redman, 1996; Elder, 1992). Finally, the presence of abdominal ascites or a ventriculoperitoneal shunt increases the chances of developing an inguinal hernia (Grosfeld et al., 1991).

Diagnosis

Signs and Symptoms

Inguinal hernias and communicating hydroceles typically manifest as a painless bulge found in the groin or extending along the cord to the scrotum. The bulge may be present only during periods of increased intra-abdominal pressure (crying or bowel movements); the supine position facilitates reduction of peritoneal fluid and intra-abdominal contents. **The presence of an intermittent bulge helps to distinguish a reducible inguinal hernia and communicating hydrocele from a scrotal hydrocele or hydrocele of the spermatic cord.** The child with an incarcerated inguinal hernia will be irritable or inconsolable and have a persistent or larger bulge without spontaneous reduction and may have decreased appetite and signs of bowel obstruction (abdominal distention, vomiting, and lack of flatus or stool).

The scrotal hydrocele may be seen as a chronic or acute scrotal swelling after an inflammatory, infectious, or traumatic event. The hydrocele size is typically stable but may decrease over time. The hydrocele of the spermatic cord is also usually painless and variable in size. It may be confused for the testis because of its round-oval shape.

Physical Examination

Physical examination starts with a child standing (Fig. 44.28), if age appropriate, otherwise supine. Inspection proceeds from the lower abdominal skin crease and along the inguinal canal to the scrotum. If the child is crying, the bulge should be assessed to emerge or increase in size and then improve or disappear when the child is consoled. Techniques to increase intra-abdominal pressure may induce protrusion of the bulge (immobilizing the extremities to induce crying in infants, and jumping, coughing, laughing, blowing bubbles, or blowing up balloons in older children) (Brandt, 2008). **If a bulge is not elicited at the time of examination, photographs of the bulge taken by family members are diagnostically reliable** (Kawaguchi and Shaul, 2009).

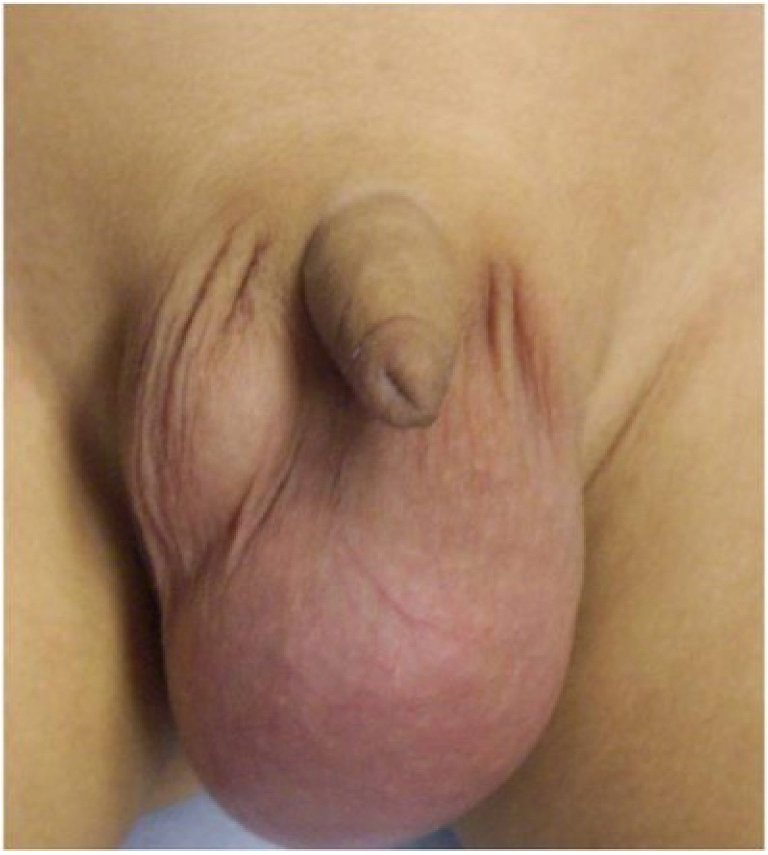

FIG. 44.28 Inguinoscrotal swelling of the left side with child in the standing position. The fluid-filled area was reduced into the abdomen with the child in the supine position.

Palpation proceeds craniocaudally from superior-lateral to the pubic tubercle down to the scrotum to determine the proximal and distal extent of the swelling. Communicating hydroceles and hernias start at the level of the internal ring and end variably. The silk-stocking sign (sensation of rubbing silk together), sought by rubbing the cord structures side to side near the pubic tubercle, implies thicker cord structures. A hydrocele of the spermatic cord may be confused with a testis or large epididymal cyst, but normal cord structures are palpable above and below, and a testis will also be palpated. Scrotal hydroceles may elicit a blue hue through the scrotal skin. Normal cord structures are palpable superior to the hydrocele but may be difficult to distinguish if it extends up to or across (abdominoscrotal) the internal ring, in which case abdominal examination should reveal a ballotable mass. **The hydrocele fluid surrounding the testicle should transilluminate; however, neonatal bowel may also transilluminate.** The testis should be palpable within a soft scrotal hydrocele but may be difficult to discern within a tense hydrocele.

Radiologic Imaging

Although imaging is not commonly needed, ultrasound can be helpful in ascertaining large elongated echolucent area from the groin extending anteromedially in the spermatic cord in the more obese child, confirming the presence of bowel or omentum in an incarcerated hernia, distinguishing tense hydroceles of the cord from a solid mass or from a large epididymal cyst (Fig. 44.29). **In the presence of a presumed hydrocele, a sonogram can aid in identifying an unpalpable testicle surrounded by hydrocele fluid** (Fig. 44.30).

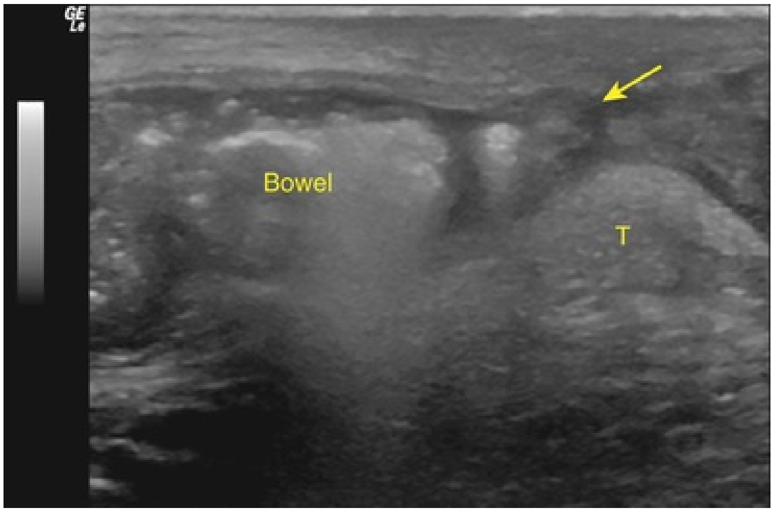

FIG. 44.29 Sagittal image of a scrotal ultrasound in a 4-year-old boy with an inguinoscrotal bulge. Bowel is seen within the hernia sac that ends *(arrow)* superior to the testis *(T)* in the scrotum.

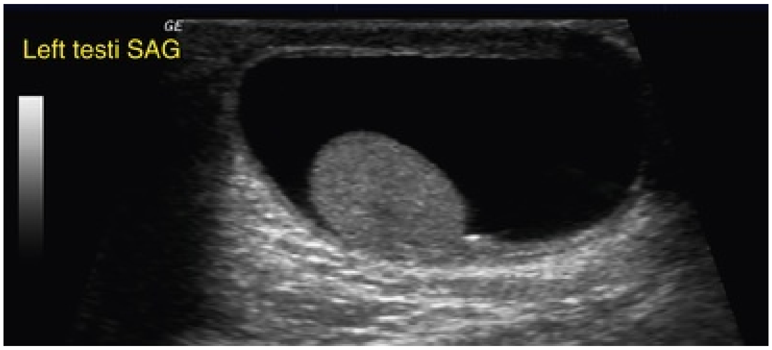

FIG. 44.30 Sagittal *(SAG)* image from a scrotal sonogram of an 8-month-old boy with tense scrotal swelling and indiscernible testis on palpation. Sonogram demonstrates hypoechoic fluid (hydrocele) surrounding the normal testis.

Surgical Repair

Inguinal Hernia

Inguinal hernias require surgical repair shortly after diagnosis, given the significant risk of associated complications. Outpatient surgery can be performed within a few weeks in easily reducible hernias or communicating hydroceles and more urgently if there is moderate difficulty in reducing the hernia contents. Parental counseling regarding the signs and symptoms of incarceration and its possible consequences should occur. An irreducible hernia requires immediate exploration. Hernias in premature infants can be repaired before hospital discharge, but repair may have to be delayed in extremely low–birth-weight (<1500 g) infants or those with congenital heart disease, pulmonary disease, sepsis, or metabolic disease because of the increased risk of anesthesia. Some authors recommend delaying surgery until 50 to 52 weeks postconception rather than performing surgery before hospital discharge (Chen et al., 2009; Stylianos et al., 1993).

Hydroceles

Hydroceles in infants have the potential to resolve spontaneously. If the hydrocele persists by age 1 year or if during the period of observation, the hydrocele enlarges or begins to fluctuate in size, implicating the development of a communicating hydrocele/hydrocele, then surgery is indicated. Hydroceles of the spermatic cord do not tend to resolve spontaneously but rarely require urgent surgery and can also be corrected after age 1 year.

Standard Inguinal Hernia Repair

The traditional surgical approach to repairing an indirect inguinal hernia or communicating hydrocele, high ligation of the hernia sac at the level of the internal inguinal ring, carries high success rate, low morbidity, limited postoperative pain, and good cosmesis. A small incision is made in the Langer lines at the skin crease superolateral to the pubic tubercle (Kogan, 2007). The Scarpa fascia is incised to expose the external oblique fascia, which is then cleared laterally and caudally to the external inguinal ring. The external oblique fascia is opened in the direction of its fibers, with care taken to avoid injuring the ilioinguinal nerve. In young infants, the internal and external inguinal rings are in proximity, providing adequate access without opening of the external oblique fascia (Mitchell-Banks technique; Kurlan et al., 1972). The cremaster muscle fibers are separated perpendicular to the cord to expose the hernia sac anteromedially. The sac is elevated and separated atraumatically from the rest of the cord and then divided between clamps. The proximal limb is elevated and separated from the cord proximally to the internal ring, where it is ligated to avoid risk of recurrence. If there are contents present or suspected, or if the sac is large or thickened, it should be opened before ligation to confirm the absence of any tissue or to reduce bowel, omentum, or a sliding component. The internal ring should be tightened medially without compressing the cord in cases of significant widening (Brandt, 2008; Ein et al., 2006). When the distal sac is short, it may be left in place, and when long, the anterior aspect can be excised. A hydrocele should be excised and any appendages removed.

In peripubertal boys with hydrocele, an inguinal approach is preferred if there is clinical evidence of a communicating hydrocele; otherwise a trans-scrotal hydrocele repair is performed as in adults, and an inguinal incision is made only if a proximal communication is identified. In a retrospective study, Wilson et al. (2008) recorded the intraoperative findings of children undergoing hydrocele repair and found hydroceles were noncommunicating in 82.1% of children older than 10 years and in 86.4% of children older than 12 years. Age was significantly associated with a patent processus vaginalis.

Complications

Early postoperative complications, including bleeding and infection, are rare after standard hernia repair. **The rate of recurrent inguinal hernia after uncomplicated open repair is 0.5% to 1%** (Farrow and Thompson, 1963;

Grosfeld et al., 1991; Vogels et al., 2009; Wright, 1994; Zhang and Li, 1993) and rises to 2% for premature infants (Krieger et al., 1994; Misra et al., 1994) and 3% to 6% after repair of an incarcerated hernia (Clatworthy et al., 1954; Farrow and Thompson, 1963). Recurrence typically occurs within 1 year for 50% of the patients and by 2 years for more than 75% (Grosfeld et al., 1991; Wright, 1994). **The causes of recurrent hernias include failure to properly identify or ligate the sac during the original procedure; a tear in the sac, leaving a strip of peritoneum along the cord; damage to the floor; or a missed direct hernia at the original exploration.** Interestingly, Tabrizian et al. reported on a cohort of patients whose repair did not include high ligation to avoid injury to adjacent organs or vessels, and no hernia recurred over a 1- to 3-year follow-up period (Tabrizian et al., 2013).

Surgical repair of recurrent hernias can usually be accomplished inguinally with ligation of an indirect sac at the level of the internal inguinal ring and/or repair of the floor of the inguinal canal for a direct hernia.

The incidence of complications related to the genital tract, secondary cryptorchidism, testicular atrophy, and vasal injury is not well defined. **If a testis is incompletely descended or retractile, orchidopexy should be performed at the time of herniorrhaphy**. Iatrogenic cryptorchidism is avoidable (Kaplan, 1976; Puri et al., 1984) by confirming proper testis position on completing the herniorrhaphy. The risk of testicular atrophy was 0.3% in the large single center series (Ein et al., 2006) but ranged from 4% to 12% in other series (Clatworthy et al., 1954; Rowe and Clatworthy, 1970), with higher rates among the irreducible cases (Fasching and Hollwarth, 1989). The causes include compression of the gonadal vessels by the irreducible hernia or vascular damage incurred during surgical repair. Young infants are at higher risk with infarction rates of 30% to 33% (younger than 2 or 3 months) (Fasching and Hollwarth, 1989; Slowman and Mylius, 1958). **Portions of vas deferens are found in 0.13% to 0.3% of cases, although embryonal remnants not representing true ductal structures are much more common (1.5% to 2.9%)** (Partrick et al., 1998; Popek, 1990; Steigman et al., 1999). The risk of vasal injury may be higher in young infants and/or cases of incarceration. Vasal injury without transection may manifest as vasal obstruction and infertility later in life (Sheynkin et al., 1998).

Persistence of a hydrocele is rare after decompression at the time of hernia repair (0.1% in the series by Ein et al. [2006]) and should be observed for spontaneous resolution for at least 1 year. If persistent, secondary scrotal hydrocele repair is indicated, or reoperative hernia repair if fluctuation suggests a recurrent hernia.

Scrotal Approach to Inguinal Hernia Repair

Concurrent with reports advocating a scrotal approach to orchidopexy, some authors suggest a similar approach to inguinal hernia and communicating hydrocele (Fearne et al., 2002; Gokcora and Yagmurlu, 2003; Lais and Ferro, 1996). For bilateral inguinal hernias, Shih described a median raphe approach (Shih and Uen, 2012). Initial data suggest no major differences in success rate or morbidity using the scrotal approach compared with standard inguinal surgery but offer a more rapid operation and cosmetic benefit (Alp et al., 2014). Fearne et al. (2002) ligated the processus vaginalis at the level of the external inguinal ring in 195 boys and saw one recurrence (mean follow-up, 13 months). Issues related to the level of sac ligation and patient age have not been fully addressed (Wilson et al., 2008) and deserve longer-term follow-up.

Laparoscopic Inguinal Hernia Repair

Laparoscopic hernia repair uses two major techniques: peritoneal closure of the defect (Schier, 2006) and an extraperitoneal approach (Endo et al., 2009; Takehara et al., 2006), which has gained interest over the past several years. In a meta-analysis of 10 comparative studies of laparoscopic versus open inguinal hernia repair in 2699 infants and children, Alzahem (2011) noted that laparoscopic techniques were associated with a trend toward higher recurrence rate, longer operative time for unilateral repairs, and shorter operative time for bilateral repairs. There was a significant reduction in development of a contralateral metachronous inguinal hernia in the laparoscopic group (Alzahem, 2011). These conclusions have been confirmed in more recent studies, but the recurrence rates have begun to approach those of open repair (Esposito et al., 2014a; Miyake et al., 2016; Timberlake et al., 2015).

Surgery can be performed efficiently, but the recurrence risk remains higher (up to 4%) than with open repair, although it may decrease with increasing experience (Saranga Bharathi et al., 2008). A minimum of 20 cases is suggested to reach the learning curve plateau (Bertozzi et al., 2013). The use of nonabsorbable suture material also decreases the recurrence risk (Grimsby et al., 2015).

Conflicting literature exists regarding levels of pain and operative time after laparoscopic repair (Chan et al., 2005; Koivusalo et al., 2009). Laparoscopic repair of recurrent inguinal hernias was reported by Shalaby et al. (2015b) in 38 patients as efficient, safe, and successful. Despite the growing literature on the utility and possible benefits of laparoscopic hernia repair, a recent survey of 187 European pediatric surgeons, of whom 85% were senior surgeons, 80% of experienced laparoscopists (performed more than 100 cases annually and performed laparoscopy for other conditions) revealed that an open approach was predominantly favored (83%) because of the lower risk of recurrence and of injury to adjacent structures. Only 17% preferred laparoscopic hernia repair, but 58% would perform it on all patients regardless of age, and only 15% would employ this approach for cases of incarceration. Laparoscopy was preferred because of less metachronous contralateral hernias (57%), better cosmesis (41%), easier technique (34%), less vas/vessel injury (31%), and less postoperative pain (22%) (Zani et al., 2014).

Key Points: Hernias and Hydroceles

- Inguinal hernias develop in 1% to 5% of children, more commonly in boys and premature infants. The propensity for the right side (3:1) is attributed to the later descent of the right testicle. Female gender, prematurity, age younger than 1 year, and history of cryptorchidism are risk factors for bilaterality.
- An intermittent bulge helps to distinguish a reducible inguinal hernia and communicating hydrocele from a scrotal hydrocele or hydrocele of the spermatic cord. If a bulge is not elicited at the time of examination, photographs of the bulge taken at home are diagnostically reliable.
- Inguinal hernias should be repaired soon after diagnosis, whereas hydroceles can often resolve spontaneously and warrant a period of observation.
- Surgical repair can be performed through an inguinal, scrotal, or laparoscopic approach. The inguinal approach carries the highest success rates at this time.
- The causes of recurrent hernias (0.5%–1%) include failure to properly dentify or ligate the sac during the original procedure; a tear in the sac, leaving a strip of peritoneum along the cord; damage to the floor; or a

missed direct hernia at the original exploration.

- Transperitoneal diagnostic laparoscopy offers a rapid, direct, and accurate inspection of the contralateral internal inguinal ring.

Despite the previously mentioned considerations, efforts have been made to reduce the size (Turial et al., 2011b) and number of ports and to apply the techniques to younger and more complex patients. Whereas the standard laparoscopic approach uses three ports, some authors report similar outcomes using two ports (Xu et al., 2013) or even a single port (Chang et al., 2012; Li et al., 2012; Shalaby et al., 2015a; Shen et al., 2010). Turial et al. (2011a) reviewed their experience in 147 infants who weighed 5 kg or less, using either a 5-mm scope or a microlaparoscope and 2-mm instruments. The median operative time for the bilateral hernia was 20 minutes. Hernias recurred in 2%, with a higher risk for those with an American Society of Anesthesiologists (ASA) score of 3 or more. No cases of testicular atrophy occurred, and high testes requiring surgery occurred in 4%, which was inversely related to body weight. Esposito et al. (2010) performed outpatient laparoscopic inguinal hernia repair on 50 children younger than 1 year. After division of the sac distal to the ring, the peritoneum was closed using a purse-string suture of a nonabsorbable material. The median operating time was 22 minutes (unilateral, 7 to 30; bilateral, 12 to 42) with one recurrence. Recurrence rates may be equal (Hughes et al., 2016), lower in those younger than 1 year than in older children (Choi et al., 2012). Multiple reports have been published regarding a laparoscopic approach to the incarcerated hernia whereby the bowel is brought back into the abdomen, inspected, and the hernia closed by variable techniques (Zhou et al., 2014). Esposito et al. (2013) reported their experience with 46 patients with an incarcerated hernia (1 month to 8 years), of which more than one-half were irreducible. There were no conversions and two recurrences (4.3%) after a minimum follow-up of 14 months. They purport three main advantages of the laparoscopic approach: aversion of edematous tissue by bypassing the cord structures; bowel reduction performed under direct visual control; and inspection of the incarcerated organ at case end.

Assessment of the Contralateral Internal Ring

The need to assess the patency of the contralateral processus vaginalis or of the internal inguinal ring in children with a unilateral hernia remains

controversial. The goal of contralateral assessment is avoidance of metachronous hernia development and its attendant risks and costs. Historically, routine contralateral exploration was performed and then more selectively in patients considered at high risk for metachronous hernia based on age, prematurity, gender, or associated disease. In a survey, 51% of pediatric general surgeons stated that they routinely perform contralateral exploration in premature infants; 40% perform exploration in boys younger than 2 years, and 13% in boys ages 2 to 5 years (Levitt et al., 2002).

In contrast to older methods, **transperitoneal diagnostic laparoscopy offers a rapid, direct, and accurate inspection of the contralateral internal inguinal ring** (Fig. 44.31). A meta-analysis of 964 laparoscopic evaluations identified a sensitivity of 99.4% and specificity of 99.5%. The incidence of an open contralateral internal ring among boys younger than 1 year without a clinical hernia is 10% undergoing laparoscopic orchidopexy (Palmer and Rastinehad, 2008). Among those undergoing unilateral inguinal hernia repair, the incidence of a contralateral patent processus vaginalis ranges from 57% to 68% during open exploration and 39% to 61% during laparoscopic hernia repair (Miltenburg et al., 1998; Saad et al., 2011; Tepas and Stafford, 1986; Zona, 1996). The incidence is inversely related to age; Chin et al. (1995) found an open contralateral ring in 41% of infants younger than 1 year, in about 30% of toddlers aged 2 to 5 years, and in 19% of children older than 10 years. The incidence in adults at autopsy is 20% (Ajmani and Ajmani, 1983).

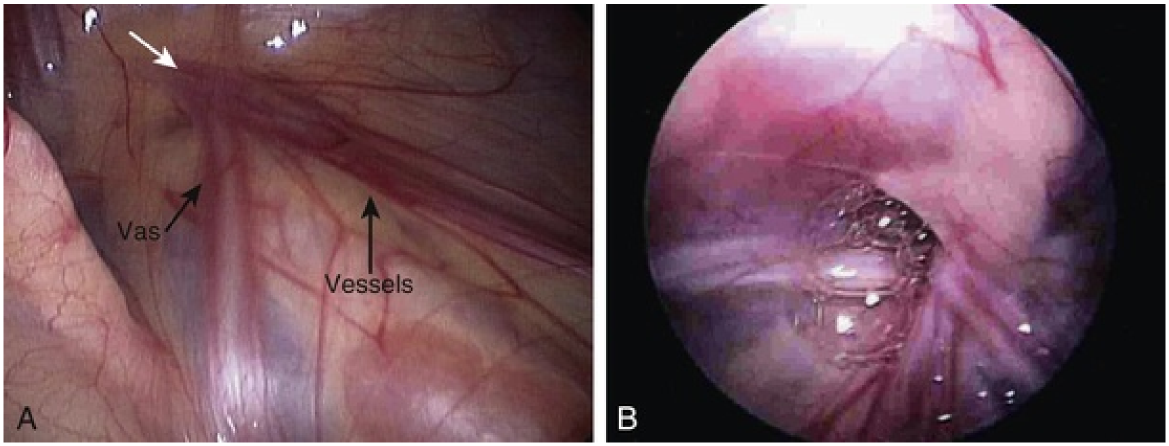

FIG. 44.31 Transinguinal laparoscopic views of (A) a closed *(white arrow)* and (B) an open contralateral internal inguinal ring. Note the bubbles emanating from the air pushed back through the open ring.

The incidence of metachronous development of an inguinal hernia is low. A meta-analysis by Miltenburg et al. (1997) of studies including patients in whom the patency status of the contralateral ring was unknown reported a 7% risk of developing a metachronous contralateral hernia, with 90% developing within 5 years of the initial repair. A systemic review by Ron et al. (2007) confirmed this incidence. Among 1291 children whose contralateral ring was deemed closed by transinguinal laparoscopy, 2.5% had a metachronous contralateral hernia 12.2 months (median) later (Juang et al., 2012), and at the time of unilateral laparoscopic hernia repair 3.1% of 293 children at a median of 24 months of age (range, 6 to 42 months; Tam et al., 2013). **Unfortunately, these studies offer indirect insight into the natural history of an open internal ring, and the question of the natural history of such a ring will remain unanswered until a prospective study of known open contralateral internal inguinal rings is conducted.**

Abdominoscrotal Hydrocele

Abdominoscrotal hydroceles are uncommon, accounting for 1.25% of all hydroceles in a large series (Avolio et al., 2000), and are bilateral in about 30% of cases (Belman, 2001; Bayne et al., 2008; Cozzi et al., 2008; Ferro et al., 1995; Nagar and Kessler, 1998). These noncommunicating scrotal masses are tense and extend into the abdomen, where they may be palpable. Ultrasound may aid in defining the proximal extent (Belman, 2001). Abdominoscrotal hydroceles usually manifest in infancy as such or as scrotal hydroceles that enlarge over time (Celayir et al., 2001; Cuervo et al., 2009), improve (Cozzi et al., 2008), or resolve spontaneously (Upadhyay et al., 2006). Associated diagnoses include cryptorchidism, contralateral hernia, hydrocele, or vanishing testis.

The most likely cause is enlargement and extension of a scrotal hydrocele into the retroperitoneal or properitoneal space after closure of the processus. Bayne et al. (2008) found that abdominoscrotal hydrocele fluid was exudative and theorized that increasing size and pressure would lead to lymphatic obstruction and progression. Massive enlargement could extend into the upper abdomen and be associated with hydroureteronephrosis, lower extremity edema, or appendicitis (reviewed by Cuervo et al., 2009). Chamberlain et al. (1995) first reported dysmorphic elongation of the testis; this was subsequently confirmed (Bayne et al., 2008) but found to be reversible in most cases (Cozzi et al., 2008).

The traditional surgical approach is an inguinal incision with proximal dissection of the sac from its abdominal attachments and distal complete or partial mobilization, with or without orchidopexy. Some authors advocate orchidopexy to avoid iatrogenic cryptorchidism (Bayne et al., 2008; Nagar and Kessler, 1998). Aspiration of the scrotal component may facilitate the proximal dissection (Cuervo et al., 2009). Alternative approaches include a midline abdominal approach for large bilateral cases (Serels and Kogan, 1996) or laparoscopic decompression of the abdominal component followed by inguinal excision (Abel et al., 2009). To avert injury to the spermatic cord or vas, a strip of the lining of the sac may be left along the cord (Cuervo et al, 2009; Ferro et al., 1995). Tightening of a patulous internal ring is described but may be unnecessary because the processus vaginalis is invariably closed.

Belman (2001) described a primary scrotal approach with drainage, excision, and extensive plication with limited dissection. Cozzi et al. (2008) reported reduced morbidity and similar efficacy for the scrotal approach (5 patients) compared with the inguinal approach (13 patients). Persistent scrotal swelling, hematoma, and undescended and/or hypoplastic testis was reported in 11 inguinal cases and infection in 2 scrotal cases.

Acute Scrotum

Acute scrotum refers to the **constellation of new onset of pain, swelling, and/or tenderness of intrascrotal contents.** There is a limited differential diagnosis (Box 44.2) with considerable overlap of signs and symptoms, which may affect the ability to make a definitive diagnosis; some reliable clinical features exist, and adjuvant use of scrotal imaging is helpful in making a diagnosis. **Torsion of the appendix testis is the most common diagnosis** (40% to 60%), followed by spermatic cord torsion (20% to 30% excluding neonates), epididymitis (5% to 15%), and other or no pathology (10%) (Anderson and Giacomantonio, 1985; Mäkelä et al., 2007; Mushtaq et al., 2003; Murphy et al., 2006; Sidler et al., 1997; Van Glabeke et al., 1999). Although all of these diseases can occur at any time during childhood, appendage torsion is typically most common after infancy and before puberty, whereas epididymitis and spermatic cord torsion are most common in the perinatal and pubertal periods. Torsion of an appendage and epididymitis are managed conservatively with limited consequence; prompt surgical exploration for testicular torsion is imperative because the gonad is at considerable risk of ischemic damage or loss, particularly when there is a delay in presentation, evaluation, or management.

Box 44.2

Differential Diagnosis of Pediatric Adolescent Acute Scrotal Pain

- Appendage torsion
  - Appendix testis
  - Other appendage (epididymis, paradidymis, vas aberrans)
- Spermatic cord torsion
  - Intravaginal, acute or intermittent
  - Extravaginal
- Epididymitis
  - Infectious
    - Urinary tract infection
    - Sexually transmitted disease

        - ?Viral
    - Sterile or traumatic
- Scrotal edema or erythema
    - Diaper dermatitis, insect bite, or other skin lesions
    - Idiopathic scrotal edema
- Orchitis
    - Associated with epididymitis with or without abscess
    - Vasculitis (e.g., Henoch-Schönlein purpura)
    - Viral illness (mumps)
- Trauma
    - Hematocele or scrotal contusion or testis rupture
- Hernia or hydrocele
    - Inguinal hernia with or without incarceration
    - Communicating hydrocele
    - Encysted hydrocele with or without torsion
    - Associated with acute abdominal pathology (e.g., appendicitis, peritonitis)
- Varicocele
- Intrascrotal mass
    - Cystic dysplasia or tumor of testis
    - Epididymal cyst, spermatocele or tumor
    - Other paratesticular tumors
- Musculoskeletal pain from inguinal tendonitis or muscle strain
- Referred pain (e.g., ureteral calculus or anomaly)

Delay in presentation for medical attention may stem from patient embarrassment or denial but also from **lack of public awareness regarding torsion and the possible consequences**. Ubee et al. (2014) surveyed parents of 62 boys undergoing emergent scrotal exploration, among whom 66% did not fully appreciate the implications of acute scrotal pain and who overwhelmingly (96%) felt increased public awareness of the condition was needed. In a survey of more than 500 parents in a nonurgent setting, Friedman et al. (2016a) found 34% had heard of testicular twisting/torsion, most commonly through friends, relatives, or knowing someone with torsion (35%) and only 17% from their pediatrician. Only 13% of parents had spoken with their children about torsion. In response, these authors presented an electronic module aimed at educating health care providers on the evaluation and differential diagnosis of acute scrotal pain that was learned within 30 minutes, increased confidence in assessment (Friedman et al., 2016b), and produced a publicly available educational video regarding testis torsion aimed at patients and families (https://www.healthychildren.org/English/health-issues/conditions/genitourinary-tract/Pages/Testicular-Torsion.aspx).

Spermatic Cord Torsion

Acute Intravaginal Spermatic Cord Torsion

Predisposing Factors.

Intravaginal torsion is commonly attributed to excess mobility of the testis within a “bell-clapper deformity,” wherein the tunica vaginalis abnormally fixes proximally on the cord. Although found in 12% of males at autopsy (Caesar and Kaplan, 1994a), the prevalence of torsion is much lower: 8.6 per 100,000 males aged 10 to 19 per year in the United States (Mansbach et al., 2005). There is evidence for a familial predisposition (Collins and Broecker, 1989; Cubillos et al., 2011; Cunningham, 1960) for which the transmission is unknown. Cubillos et al. (2011) found a family history (various relatives) in 10% of probands, including one family with three generations of torsion. **The inciting event for torsion is unknown** but may include cold temperature (Chiu et al., 2012; Lyronis et al., 2009; Srinivasan et al., 2007) even in tropical countries (Gomes et al., 2015) or a change in temperature (Chen et al., 2013) activating the cremasteric reflex, and/or rapid testicular growth at puberty; yet torsion may occur at rest or at sleep. **Cryptorchid testes are at increased risk of torsion and difficult to assess because of the high position.** Torsion after previous orchidopexy may be related to failure of suture (absorbable or nonabsorbable suture) to fix the testis in place (Frank and O'Brien, 2002; Mor et al., 2006; Redman and Barthold, 1995).

Clinical Presentation.

Intravaginal testicular torsion may occur at any age, but the vast majority of cases occur after age 10 years with a peak at 12 to 16 years (Anderson and Giacomantonio, 1985; Mäkelä et al., 2007; Mansbach et al., 2005; Murphy et al., 2006; Mushtaq et al., 2003; Sidler et al., 1997). The prevalence of testicular torsion is 1 in 4000 (Williamson, 1976) with left-sided predominance and rare bilaterality. Classically, boys complain of acute, severe scrotal pain that occurs at rest (even sleep) or with physical activity or after trauma. **A history of prior episodes may be elicited.** Alternatively, patients may have milder, less acute, or even absent scrotal pain or may have inguinal or abdominal pain. Nausea and vomiting occur in 10% to 60% of boys (Jefferson et al., 1997; Knight and Vassy, 1984; Mäkelä et al., 2007; Sessions et al., 2003; Williamson, 1976). Scrotal edema and erythema may be present, depending on the duration or degree of torsion. Dysuria and fever are uncommon.

The most common physical findings are generalized testicular tenderness, abnormal orientation of the testis, and absent cremasteric reflex. Inspection may identify the high-riding testis from a foreshortened cord and horizontally oriented testis. The genitofemoral reflex arc, normally present after age 2 years (Caesar and Kaplan, 1994b), is elicited by scratching the inner thigh with resultant testis elevation. Some studies report reduced or absent reflex in all cases of testicular torsion (Caldamone et al., 1984; Kadish and Bolte, 1998; Rabinowitz, 1984), but it was intact in up to 10% of proven cases of torsion in other series (Hughes et al., 2001; Karmazyn et al., 2005; Murphy et al., 2006; Nelson et al., 2003). The presence of a **cremasteric reflex correlates with intact testicular blood flow but does not unequivocally indicate normal testicular perfusion, especially if the clinical presentation is otherwise suggestive of torsion.** Although anterior epididymal position, thickening of the cord, testicular induration, loss of boundaries between the testis and epididymis, scrotal edema, and/or erythema may be present, landmarks become obliterated and the examination less reliable as the duration of torsion increases.

Several efforts have been made to offer a better clinical assessment of testicular torsion in patients with the acute scrotum. Using a standardized history and physical examination form, Srinivasan et al. (2011) found that absence of ipsilateral cremasteric reflex, nausea or vomiting, and scrotal skin changes on multivariate analysis were predictive of testicular torsion. According to use of a decision tool, patients with acute (<72 hours) scrotal pain and all of the following had no risk of testicular torsion (100% sensitivity and negative predictive value): normal testicular lie, lack of nausea and vomiting, and age 0 to 10 years (Shah et al., 2013). Barbosa et al. (2013) developed a scoring system based on testicular swelling, hard testicle, absent cremasteric reflex, nausea or vomiting, and high-riding testis, which was validated by Sheth et al. (2016). In an effort to reduce in-hospital delay, a standardized process was used at Texas Children's Hospital that included a sign and symptom scoring tool for stratifying risk and improving communication that allowed significantly reduced time from emergency department or ultrasound suite to the operating room (Afsarlar et al., 2016).

Diagnostic Studies.

Urinalysis is of limited usefulness in cases of testicular torsion but is used to identify pyuria and/or bacteriuria associated with epididymitis or hematuria, implicating a urinary tract calculus. Before the advent of reliable and rapid scrotal imaging, immediate scrotal exploration was routine. Radionuclide imaging carried about 90% sensitivity and specificity but was lengthy, was not readily available, and used ionizing radiation, and is currently rarely used. Ultrasound offered a rapid, available, and safe modality to assess testicular architecture, intraparenchymal blood flow, and other anatomic details (hydrocele, scrotal thickening).

CDUS findings consistent with testicular torsion include reduced or absent Doppler color or waveforms and parenchymal heterogeneity compared with the contralateral testis (Fig. 44.32). Kaye et al. (2008b) and later Chmelnik et al. (2010) found that all **testes with heterogeneous echogenicity were necrotic, whereas homogeneous echogenicity predicted a lower risk of orchiectomy.** Lack of demonstrable intratesticular flow on CDUS is 86% sensitive, 100% specific, and 97% accurate in the diagnosis of torsion and ischemia in painful scrotum (Burks et al., 1990) and its use spread (Kass et al., 1993b); even current studies reflect the accuracy of this approach. Altinkilic et al. (2013) prospectively assessed the diagnostic value of CDUS in patients with clinical suspicion of torsion who were explored by a surgeon blinded to the CDUS results. The sensitivity, specificity, and positive and negative predictive values of CDUS for detecting testicular torsion were 100%, 75.2%, 80.4%, and 100%, respectively. The authors concluded that routine surgical exploration was unnecessary if CDUS reveals normal intratesticular perfusion. However, in other studies the sensitivity in confirming decreased or absent blood flow in proven cases of spermatic cord torsion was only 63% to 90%, possibly because of enhanced detection of flow with newer equipment and/or user-dependent characteristics (Bentley et al., 2004; Kalfa et al., 2004; Karmazyn et al., 2005; Stehr and Boehm, 2003; Steinhardt et al., 1993). Cassar et al. (2008) evaluated Doppler waveforms in cases of torsion with decreased or preserved testicular flow and observed subtle waveform abnormalities, including increase or decrease in amplitude relative to the normal testis and reversal of diastolic flow. Increased epididymal size and/or echogenicity and altered epididymal vascularity, usually absent or reduced but occasionally increased, may provide additional support for the diagnosis of torsion (Nussbaum et al., 2006).

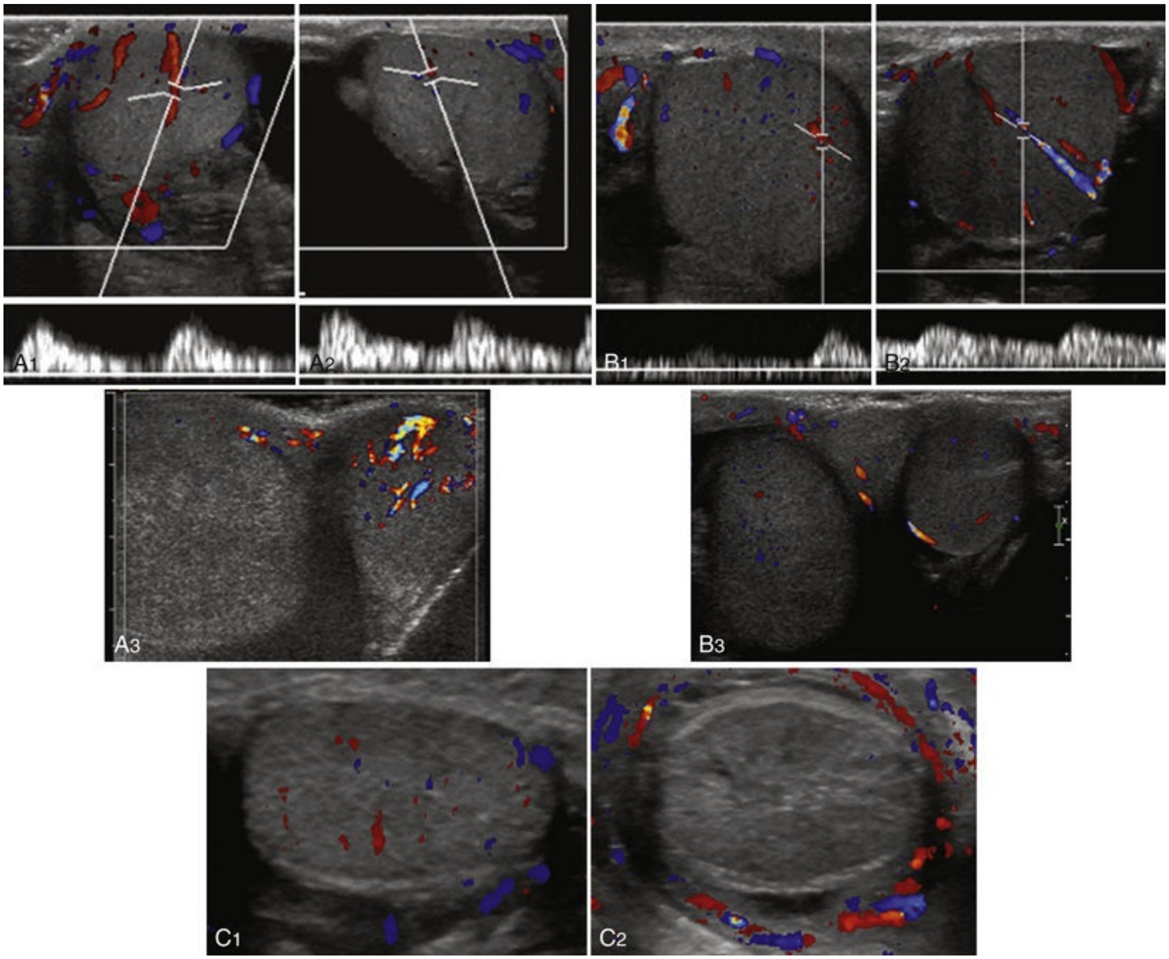

FIG. 44.32 Imaging of intravaginal spermatic cord torsion. (A) Intermittent torsion. Color Doppler ultrasonography (CDUS) demonstrates preserved arterial flow to testis with 12 hours of pain and then loss of flow and parenchymal heterogeneity when child returned later with worsening pain. (B) Acute torsion with reduced arterial flow. (C) Prolonged torsion. CDUS shows heterogeneous testis without arterial or venous flow and a hyperechoic parenchymal ring.

High-resolution (10- to 20-mHz probe) ultrasonography (HRUS) of the length of the spermatic cord may enhance the ability to diagnose torsion. Using HRUS to directly image the cord proximal to the testis, Kalfa et al. (2004) visualized the cord twist as a 1- to 3-cm snail-shaped mass in 43 patients and a completely linear cord in nontorsion cases (Fig. 44.33). In a multi-institutional retrospective series of 919 cases of acute scrotum with cord imaging by HRUS, a cord twist was seen in 96% of cases of surgically proven torsion, and HRUS carried 99% specificity when the cord was linear (Kalfa et al., 2007). However, Karmazyn et al. (2005) observed normal testicular blood flow and no visible spermatic cord twist in 2 of 41 boys with partial or intermittent torsion.

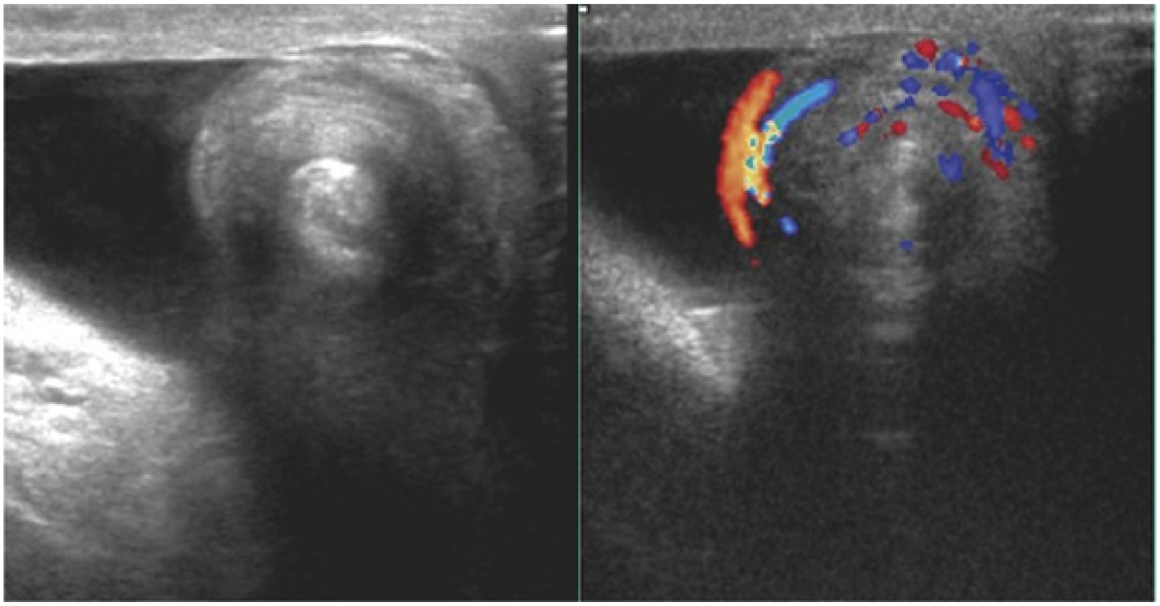

FIG. 44.33 Snail sign. B-Mode *(left)* and color Doppler ultrasonography *(right)* images showing hyperechoic central body of the snail and coiling of blood within the distal spermatic cord around the central echogenic “body.”

Potentially useful diagnostic modalities include contrast-enhanced pulse-inversion ultrasonography (CEUS), infrared thermography and spectroscopy, and scrotal MRI. Pulse-inversion imaging in a rabbit model showed superior quantitative assessment of perfusion of the experimentally torsed testis as compared with conventional CDUS (Paltiel et al., 2006). CEUS was performed in 50 patients with acute scrotal pain or trauma in whom testicular lesion of undefined nature was found at CDUS. Sensitivity and specificity were 76% and 45% for CDUS and 96% and 100% for CEUS, respectively (Valentino et al., 2011). Infrared thermography showed significant reduction in scrotal temperature by 1 hour after 720-degree torsion and prompt normalization with detorsion in a sheep model (Capraro et al., 2008). Transscrotal near infrared spectroscopy was able to reliably discriminate torsion from nontorsion in a select group of children with acute testis pain (Schlomer et al., 2017). MRI has been used in a small series of testicular torsion and may have a role in difficult diagnostic cases with use of dynamic contrast-enhanced MRI, which requires gadolinium (Mäkelä et al., 2011), or diffusion-weighted imaging with findings of a lower testicular apparent diffusion coefficient (ADC) without the need for contrast (Maki et al., 2011).

Management and Surgical Treatment

Testicular torsion is a true surgical emergency because testis viability is inversely related to duration of torsion. Visser and Heyns (2003) amassed data from a published series including 1140 patients and found that the risk of orchiectomy was approximately 5%, 20%, 40%, 60%, 80%, and 90% at 0 to 6, 7 to 12, 13 to 18, 19 to 24, more than 24, and more than 48 hours after onset of pain, respectively. The degree of torsion may provide incomplete vascular occlusion, helping to explain the variability of these data or have a multiplicative effect on the time course to testis loss (Dias et al., 2016).

Orchiectomy after surgical detorsion occurs in 30% to 70% in large studies (Kaye et al., 2008b; Mäkelä et al., 2007; Murphy et al., 2006; Sessions et al., 2003) and in 32% to 42% in database reviews (Cost et al., 2011; Mansbach et al., 2005; Zhao et al., 2011). Sessions et al. (2003) found that the **median degree of rotation was 540 degrees in orchiectomy testes and 360 degrees when the testis was salvaged,** with a range of 180 to 1080 degrees in both groups. The risk of delayed atrophy after orchidopexy was less than 10%, 40%, and 75% after less than 12, 12 to 24, and more than 24 hours of pain, respectively (Visser and Heyns, 2003). Partial (<25%) testicular atrophy may occur after operative detorsion even after 4 hours after the onset of pain (Anderson and Williamson, 1986; Krarup, 1978; Sessions et al., 2003; Tryfonas et al., 1994). Among 37 patients with at least 6 months' follow-up, Lian et al. (2016) found that 54% developed testicular atrophy (>50% compared with contralateral testis) even when deemed viable intraoperatively; duration of pain of more than 1 day and sonographic parenchymal heterogeneity were predictive of subsequent atrophy. **Preoperative manual cord detorsion may relieve symptoms and allow delayed orchidopexy but may incompletely untwist the cord.** Sessions et al. (2003) found that lateral twisting (rather than medial untwisting) occurred in 33% and manual detorsion failed to completely relieve torsion in 32% of orchidopexy cases.

There are two management approaches to the acute scrotum. One is to avoid delay and perform exploration in almost all boys to confirm absence of torsion; this implies many unnecessary surgeries (Anderson and Giacomantonio, 1985; Mäkelä et al., 2007; Mushtaq et al., 2003; Sidler et al., 1997; Watkin et al., 1996). The other approach is more selective of patients for surgical exploration (Caldamone et al., 1984; Kass et al., 1993b; Kalfa et al., 2004; Lam et al., 2005) based on the history, physical examination, and CDUS findings, which may lead to testis loss because of atypical presentation and/or false-negative imaging. **When findings support or raise suspicion for spermatic cord torsion, emergent scrotal exploration is indicated and should not be delayed.**

Surgical exploration of the testis through a hemiscrotal transverse (dartos pouch) or midline raphe incision should first address the affected side. The testis is delivered and the tunica vaginalis opened to note the color of the testis, the number of rotations, and the anatomy of the tunica vaginalis. The testis is untwisted, wrapped in warm soaked gauze, and observed for improvement in color, whereas **the contralateral testis is fixed with nonabsorbable suture to reduce the risk of metachronous torsion.** The affected testis is re-examined for potential viability, and the largely subjective decision for orchidopexy or orchiectomy is made. A Doppler flow probe or incision of the tunica albuginea (Arda and Ozyaylali, 2001) with assessment of bleeding may document intratesticular flow after detorsion; however, the reliability of these assessments lacks validation. If the testis is to be retained, it is fixed either via dartos pouch or directly to the dartos with nonabsorbable suture. Kutikov et al. (2008) have suggested that a compartment syndrome contributes to testicular injury based on the improved appearance and lower intraparenchymal pressures seen after detorsion and tunica albuginea incision in three cases. A patch of vascularized tunica vaginalis was placed in the tunica albuginea defect to maintain lower intraparenchymal pressure and to reduce the likelihood of ongoing ischemia (Fig. 44.34). Figueroa et al. (2012) applied this technique to 11 of 28 testes deemed nonsalvageable at surgery and found that 55% recovered. The long-term outcome of these patients is not available; however, in a rat model of testicular torsion, no significant histologic differences were found between a detorsion group and detorsion with tunica vaginalis flap group after 4 weeks, despite reduction of intratesticular pressure in both groups (Józsa et al., 2016; Oktar et al., 2013).

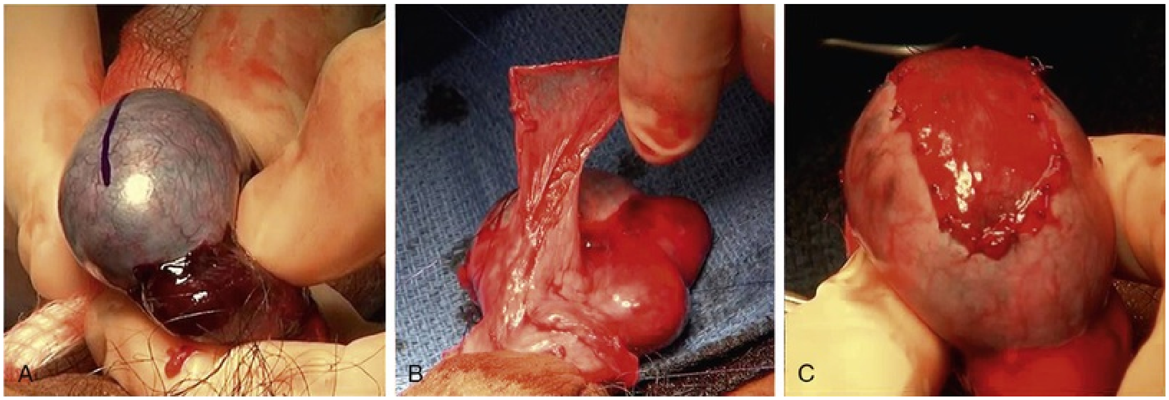

FIG. 44.34 Tunica vaginalis vascularized patch. Tense congestion of the testis (A) was relieved with incision of the tunica albuginea *(marked).* The tunica vaginalis flap on a vascularized pedicle is harvested (B) and used to fill the defect in the tunica albuginea (C). (Courtesy Douglas Canning, MD, and Jason Van Batavia, MD.)

Risk factors for orchiectomy include young age, African-American race, and being on Medicaid or lacking insurance (Cost et al., 2011; Zhao et al., 2011). Zhao et al. (2011) identified surgery at a children's unit to increase the risk of orchiectomy. This may reflect the transfer of patients, which delayed treatment by 75 minutes in the study by Bayne et al. (2010), but did not affect the orchiectomy rate in the study by Ramachandra et al. (2015). Orchiectomy is performed by dividing the cord into segments, each of which is ligated with nonabsorbable suture. In cases of orchiectomy, prosthesis placement is usually offered after complete healing or later in puberty; however, Bush and Bagrodia (2012) demonstrated the feasibility of performing concurrent prosthetic placement and orchiectomy.

Prognosis

Although the impact of testicular torsion on fertility is poorly understood given the inherent difficulty of long-term follow-up in these patients, the few available studies suggest that subtle abnormalities of semen quality are common. **Semen density is often within the normal range but correlates with shorter duration of torsion and reduced atrophy** (Anderson et al., 1992; Arap et al., 2007; Brasso et al., 1993; Fisch et al., 1988; Puri et al., 1985). The observation that increasing duration of torsion inversely correlates with semen quality and limited contralateral testicular biopsy data suggest that global testicular dysfunction may exist after torsion (Visser and Heyns, 2003). The hypothesis of an autoimmune phenomenon (Anderson and Williamson, 1990) was dispelled by analysis of antisperm antibodies in individuals with torsion (Anderson et al., 1992; Arap et al., 2007; Brasso et al., 1993; Puri et al., 1985). Available animal and human data support a role for ischemia-reperfusion injury after release of testicular torsion (Kehinde et al., 2003; Turner et al., 2004). Additional clinical data are needed to determine long-term outcome after testicular torsion and the efficacy of any adjunctive treatment. Romeo et al. (2010) assessed serum levels of FSH and LH (before and after GnRH stimulation), testosterone, and inhibin B in 20 patients 5 years (mean) after testicular torsion and in 15 age-matched controls; 12 patients were treated with detorsion and orchidopexy, and 8 underwent orchidectomy. Serum FSH, LH, and testosterone were within the reference range. Inhibin B levels were significantly reduced in the two torsion groups compared with the controls but not between each other.

Intermittent Intravaginal Spermatic Cord Torsion

Episodes of self-limited acute scrotal pain precede acute testicular torsion in 30% to 50% of patients (Stillwell and Kramer, 1986; Williamson, 1976). These episodes, single or multiple, typically begin and resolve acutely with durations of minutes to hours. Hayn et al. (2008) observed that the frequency of these episodes correlated with the risk for eventual persistent torsion and testicular loss; 71% of patients were previously diagnosed with epididymitis or appendage torsion, and 53% had acute or delayed testicular loss. Nausea and/or vomiting or notation of scrotal swelling may or may not be present. A normal vertical testicular orientation is most common (Hayn et al., 2008), but a horizontal lie may be present (Schulsinger et al., 1991). Physical findings consistent with torsion depend on whether the testis is twisted at the time of the examination. This includes the degree of tenderness and cremasteric reflexes. Eaton et al. (2005) reported absent cremasteric reflex in 3 of 15 patients and reduced or absent intratesticular blood flow by CDUS in only 5 of 12 patients. A whirlpool sign or an abnormal boggy cord and pseudomass formation below the twisted spermatic cord may also signify intermittent torsion (Munden et al., 2013).

There are challenges to confirming the diagnosis of intermittent torsion. **The diagnosis requires a high index of suspicion unless the testis is noted to untwist** during an examination or an ultrasound study shows absent or decreased flow before and normal to increased flow after marked improvement of symptoms. Once the condition is confirmed or highly suspected, **elective bilateral orchidopexy is indicated** to avert torsion and possible organ loss.

Patients and parents should know that absolute confirmation of the diagnosis may not be possible and that symptoms may persist postoperatively.

Extravaginal Spermatic Cord Torsion (Perinatal Testicular Torsion)

Perinatal spermatic cord torsion is a term applied to infants regardless of whether the event occurred prenatally (hours, days, weeks, months), during delivery, or postpartum. Torsion of the entire cord occurs before fixation of the tunica vaginalis and dartos within the scrotum (extravaginal). This event most commonly occurs well before delivery, yielding a “vanishing” testis or a hemosiderin-containing nubbin in the scrotum or less commonly in the inguinal canal. The testis that sustains loss of blood supply close to delivery is a hard, painless testis fixed to the overlying erythematous or dark scrotal skin with or without edema. A coexisting hydrocele complicates the examination. The estimated incidence is 6.1 per 100,000 births (John et al., 2008), and familial cases are reported (Castilla et al., 1975). Predisposing factors such as high birth weight and/or difficult delivery are suggested (John et al., 2008; Kaye et al., 2008a) but unconfirmed by controlled studies. In a minority of cases, symptoms occur after a documented normal scrotal examination. Rarely, neonatal intravaginal torsion occurs or infarction occurs without torsion (John et al., 2008). Bilateral torsion was noted in 5% and 22% in two series (Baglaj and Carachi, 2007; Yerkes et al., 2005) and may occur concurrently or metachronously. Several series indicate that bilateral metachronous torsion may occur in boys in whom the primary event occurs prenatally or postnatally (Al-Salem, 2007; Beasley and McBride, 2005; John et al., 2008; Yerkes et al., 2005).

Scrotal imaging may be obtained in cases of suspected perinatal torsion, but its usefulness and reliability are questionable. Prenatal ultrasonography may show torsion (Herman et al., 2002). Postnatal ultrasound may reveal parenchymal heterogeneity, calcification, and absent blood flow (Fig. 44.35; Arena et al., 2006). Reported cases of testicular blood flow suggest that postnatal CDUS may be unreliable (Al-Salem, 2007; Cuervo et al., 2007; John et al., 2008; Yerkes et al., 2005). Ultrasound helps to differentiate tumors from torsion (Kaye et al., 2008a), but its reliability in this has also been challenged (Al-Salem, 2007; Calonge et al., 2004).

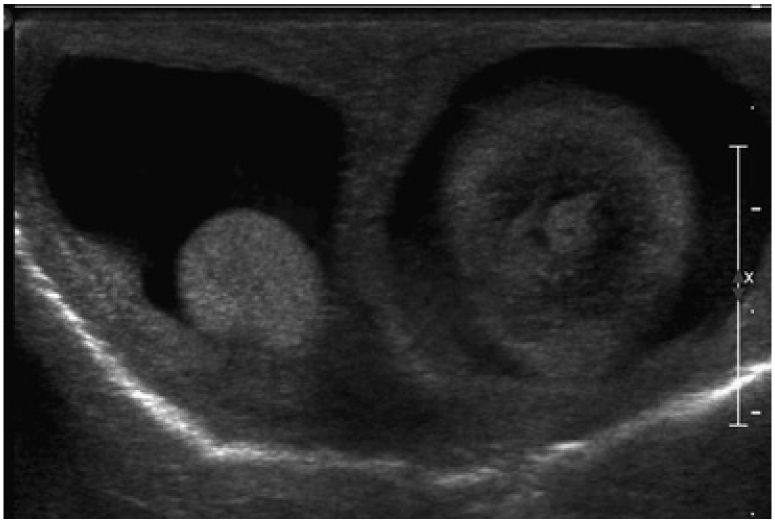

FIG. 44.35 Extravaginal spermatic cord torsion in a neonate. Transverse ultrasound image demonstrates enlarged and heterogeneous left testis and bilateral hydroceles.

There is no consensus regarding the best treatment of perinatal testicular torsion (Snyder and Diamond, 2010). One side advocates elective exploration because of the unsalvageability in most cases, the rarity of metachronous torsion, and the increased anesthetic risk (Brandt et al., 1992; Das and Singer, 1990; Kaye et al., 2008a; Stone et al., 1995). Others advocate for immediate exploration to offer possible partial or complete testicular salvage (Al-Salem, 2007; Cuervo et al., 2007; Sorensen et al., 2003) and point to cases of unexpected contralateral torsion or atrophy found at exploration (Abraham et al., 2016; Al-Salem, 2007; Baglaj and Carachi, 2007; John et al., 2008; Roth et al., 2011; Yerkes et al., 2005). Among 110 pediatric surgeons and urologists surveyed in the United Kingdom and Ireland, few (10.9%) used Doppler ultrasound to guide management or to exclude tumor. Although most (74.5%) performed ipsilateral orchiectomy and contralateral orchidopexy (71.9%), few operated emergently because a viable testis was seldom found (10%) and bilateral torsion was even rarer (7 cases). Some (21.8%) avoided contralateral orchidopexy because of concern for iatrogenic injury (Rhodes et al., 2011). **If torsion is suspected after a normal postnatal scrotal examination, then prompt exploration should be performed as for intravaginal torsion.** Some surgeons use a scrotal approach, whereas others advocate an inguinal approach to ligate a patent processus vaginalis and avoid the theoretic risk of trans-scrotal surgery if a tumor is found.

Torsion of the Appendix Testis and Epididymis

Appendage torsion is the most common cause of acute scrotum in prepubertal children. The appendix testis and appendix epididymis are vestiges of embryologic development without known function. The appendix testis (from the müllerian duct) and appendix epididymis (from the wolffian duct) are present in 76% to 83% and 22% to 28% of testes, respectively (Dresner, 1973; Jacob and Barteczko, 2005). The appendix testis, located at the cranial testicular pole or in the groove between the testis and epididymis, and the appendix epididymis, located along the caput, may be sessile or pedunculated. Although the sessile type may be more common (Jacob and Barteczko, 2005), the pedunculated type may be more prone to torsion (Jones, 1962). The cause of torsion is unknown but may be related to anatomy, trauma, and/or prepubertal enlargement.

The peak age at occurrence is 7 to 12 years (mean 8 to 9 years) (Anderson and Giacomantonio, 1985; Lyronis et al., 2009; Mushtaq et al., 2003), but the condition may occur at any age. Symptoms vary with sudden or insidious onset of pain, which may be mild or severe and intermittent with physical activity. Similarly, physical findings depend on the severity of inflammation and duration of symptoms (Rakha et al., 2006). Early on, **a “blue dot sign”** (Dresner, 1973), **a discoloration at the upper pole of the testis representing the ischemic appendage, may be seen through stretched scrotal skin** in 0 to 52% of patients (Caldamone et al., 1984; Karmazyn et al., 2005; Lyronis et al., 2009; Murphy et al., 2006; Van Glabeke et al., 1999). Murphy reported a false-positive blue dot sign in a patient with testicular torsion (Murphy et al., 2006). Other early signs include a tender nodule superior to the testis with limited testicular tenderness and symmetrical cremasteric reflexes. However, with longer duration and progressive inflammation, increased swelling and tenderness, lack of distinction between testis and epididymis, and marked scrotal wall edema and erythema may make it difficult to distinguish it from testis torsion or epididymitis.

CDUS rarely demonstrates an abnormal appendage but commonly shows hyperperfusion of the epididymis (Baldisserotto et al., 2005). Although the normal appendix testis contains no internal blood flow (Yang et al., 2005), Lev et al. (2015) noted that among 19 patients (ages 3–14 years), CDUS demonstrated a round or oval avascular lesion with heterogeneous echotexture (n = 18), posterior enhancement (n = 13), and hyperemia of the surrounding structures (n = 15). All appendages were adjacent (n = 16) or in close proximity (n = 3) to the upper pole of the testis (Fig. 44.36).

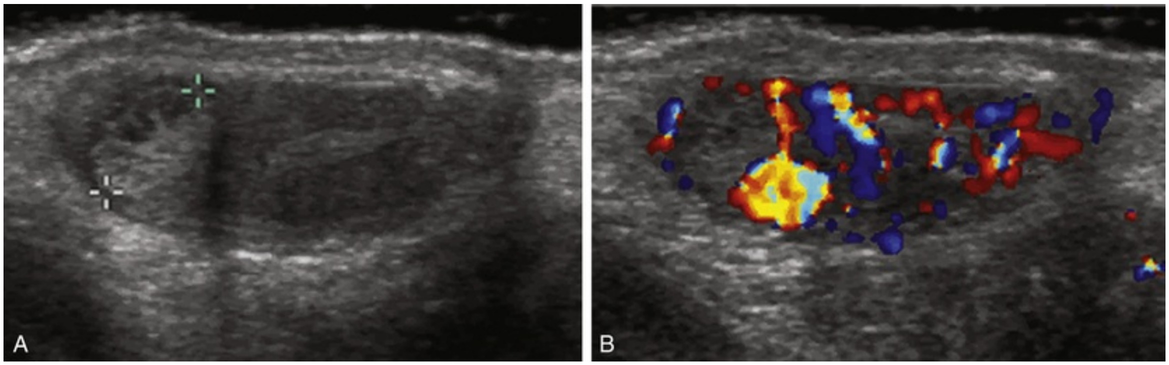

FIG. 44.36 Torsion of testicular appendage. Color Doppler ultrasonography demonstrates (A) enlarged and heterogeneous appendage and (B) absent flow despite increased flow to the epididymis and testis.

Park et al. (2011) found significant differences in the echogenicity correlated with the duration of symptom: hypoechoic in all 17 boys assessed within 24 hours of symptom onset and hypoechoic (6), isoechoic (4), or hyperechoic (8) after 24 hours.

Because **torsion of an appendage is a self-limited process** (Koff and De Ridder, 1976), surgery is rarely indicated. Treatment is aimed at reducing inflammation using ice packs and oral anti-inflammatory agents and limiting physical activity. Surgical exploration is limited to cases in which torsion of the testis is not excluded or, rarely, there is prolonged and severe pain or recurrent episodes.

Epididymitis

Epididymitis, infectious or noninfectious, is a broad category causing an acute scrotum. The incidence is poorly defined (Al-Taheini et al., 2008; Cappele et al., 2000; Lau et al., 1997; Merlini et al., 1998; Sakellaris and Charissis, 2008; Somekh et al., 2004), perhaps because children with a torsed appendage may be diagnosed with epididymitis (Kadish and Bolte, 1998; Lam et al., 2005; Lyronis et al., 2009). In many series, peaks in prevalence occur in infancy and at puberty (Mäkelä et al., 2007; Mushtaq et al., 2003; Sidler et al., 1997). Redshaw et al. (2014) noted that among 252 patients over a 21-year period, the age at first presentation was 10.92 ± 4.08 years with the majority of cases occurring during puberty (11 to 14 years) and few patients (4%) younger than 2 years old. Interestingly, 27.4% of boys experienced a second episode of epididymitis.

Classically, **the symptoms have a more insidious onset than torsion of the cord or an appendage but may present rapidly.** Fever and dysuria may or may not be present, and nausea is rare. A history of UTIs, urethral discharge, sexual activity, intermittent catheterization (Thirumavalavan and Ransley, 1992), dysfunctional voiding (Bukowski et al., 1995), urethral abnormalities (Karmazyn et al., 2009), or congenital anomalies of the ejaculatory duct (Pimpalwar et al., 2002; Yanai et al., 2005) may be present. There is a continuum on examination from localized epididymal enlargement and tenderness to massively swollen and erythematous hemiscrotum without distinct landmarks. **The cremasteric reflex should be intact.** Associated pyuria and/or bacteriuria is reported in 20% to 40% of cases (Anderson and Giacomantonio, 1985; Mäkelä et al., 2007; Murphy et al., 2006; Mushtaq et al., 2003; Sidler et al., 1997). CDUS shows increased epididymal size and blood flow as well as in the testis in some cases.

The management goal is to relieve inflammation and any associated infection. Efforts to reduce the inflammation include the use of ice packs, nonsteroidal anti-inflammatory agents, scrotal elevation, and rest to avoid traumatic exacerbation. In the absence of UTI, symptoms improve spontaneously without antibiotics (Lau et al., 1997). In the presence of pyuria, broad-spectrum antibiotics with gram-negative coverage should be used (Siegel et al., 1987), and in some cases intravenous antibiotics and hospitalization may be required. Treatment for sexually transmitted diseases should be considered, as appropriate, in adolescents.

The need to image the urinary tract has become more selective. Siegel et al. (1987) found that 47% of prepubertal boys had anomalies (urethral anomalies, ureteral ectopia) on imaging. Other clinical series have documented a low risk of urinary tract anomalies in boys with epididymitis, although infants may be at higher risk (Merlini et al., 1998; Sakellaris and Charissis, 2008). Redshaw et al. (2014) noted that anomalies were more commonly found on VCUG among boys with positive urine cultures.

Although some findings (pyelectasis, low-grade vesicoureteral reflux) may not directly contribute to epididymitis, other findings (urethral or ureteral obstruction, ejaculatory duct or vasal anomalies) are important to detect. Some authors recommend renal ultrasonography only (Al-Taheini et al., 2008) or imaging only in recurrent cases (Cappele et al., 2000). However, in **a prepubertal child with a positive urine culture, renal ultrasonography and**

voiding cystourethrography are indicated. In recurrent cases, endoscopy may reveal ejaculatory duct abnormalities undetected on voiding cystourethrography (Pimpalwar et al., 2002; Yanai et al., 2005). Recurrent epididymo-orchitis in these cases may require excision of a utricle or ejaculatory duct cyst with vasovasostomy or vasectomy.

Other Causes of Acute Scrotal Pain

Idiopathic scrotal edema manifests in prepubertal boys with unilateral or bilateral scrotal swelling with minimal or no pain (Klin et al., 2002; Lee et al., 2009). Associated findings may include local spread of erythema or edema to the inguinal or perineal region, inguinal lymphadenopathy, leukocytosis, and/or eosinophilia. The last suggests an allergic origin, although the cause is currently idiopathic. Distinctive characteristics include minimal or no pain, isolated scrotal tenderness, and thickening of the scrotal wall. The “Fountain Sign,” hypervascularity on color Doppler of the thickened scrotum depicted on transverse scans with both testes seen, is highly suggestive of the diagnosis. Because the process is self-limited, no treatment is needed, except perhaps for antihistamines (Geiger et al., 2010).

Henoch-Schönlein purpura is a systemic vasculitis affecting the skin, joints, gastrointestinal tract, and kidneys. The scrotum is involved in 2% to 38% of cases in the form of tenderness, edema, or erythema; testicular hematoma, torsion, or infarction; or cord thrombosis or epididymitis (Diana et al., 2000; Ioannides and Turnock, 2001; Turkish et al., 1976). The typical purpuric rash of the buttocks, perineum, and lower limbs is usually present but may not precede the scrotal findings. Urgent scrotal exploration is indicated if clinical findings suggest concomitant testicular torsion.

Cystic dysplasia of the rete testis is a benign lesion of the testis that was first described in 1973 by Leissring and Oppenheimer. It may present at any age but most commonly around 6 years as acute scrotal swelling and pain (Jeyaratnam and Bakalinova, 2010; Noh et al., 1999; Smith et al., 2008). Rarely, an associated ureteral anomaly may lead to chronic testicular pain (McGee et al., 2009). Ipsilateral renal dysplasia, agenesis, or ureteral anomalies are present in the majority of cases and likely represent maldevelopment of the wolffian duct. Ultrasound will reveal multiple centrally located, small cysts (2–8 mm) surrounded by compressed normal parenchyma but can involve the entire parenchyma. Magnetic resonance has been shown to be helpful (Emam et al., 2012; Landry et al., 1999). Treatment is conservative enucleation, which may be associated with recurrence, or observation; reports of spontaneous regression has been reported (Gelas et al., 2016).

Testicular rupture from trauma may cause acute scrotal pain and swelling and hematocele. CDUS is sensitive in diagnosing testicular fracture. Surgical intervention may be indicated (Adams et al., 2008), or a conservative approach may be considered (Cubillos et al., 2010), reserving surgery for cases of expanding hematoma, symptomatic hydrocele, intractable pain, absent blood flow, or abscess. In their series, Cubillos et al. reported excellent outcomes and testis salvage; slow resumption of all physical activities was reported by a minority of patients in this small cohort.

Key Points: Acute Scrotal Pain

- Delay in presentation for acute scrotal pain may stem not only from patient embarrassment or denial but also from lack of public awareness regarding torsion and the possible consequences.
- In the majority of cases in which a reliable, thorough history is taken and targeted physical examination is performed, a reliable diagnosis should be made; adjunctive ultrasound confirms a diagnosis.
- Ultrasound features suggestive of torsion of the spermatic cord include absent blood flow, a “snail sign,” and heterogeneity of the parenchyma.
- Testicular salvage rates from spermatic cord torsion are inversely related to duration and have some relationship to the degrees of torsion. Thus, in cases in which torsion is highly suspected, emergent surgery should not be delayed by imaging studies.
- Spermatic cord torsion occurring in the perinatal period are rarely salvageable when identified in the nursery and should be managed emergently when a change in physical examination has occurred.
- Appendage torsion is the most common cause of acute scrotum in prepubertal children. A “blue dot sign,” discoloration at the upper pole of the testis, may be seen through stretched scrotal skin. This is a self-limiting process requiring supportive care and analgesia management.

Varicocele

Varicocele, an abnormal dilation and tortuosity of the internal spermatic veins within the pampiniform plexus, is common among adolescents and may contribute significantly to the risk of subfertility in adulthood. Its effect on paternity is less clear because about 85% of men with varicocele in population-based studies have fathered children (Bogaert et al., 2013; Pinto et al., 1994; Safarinejad, 2008).

Epidemiology and Pathogenesis

The prevalence of clinically diagnosed varicoceles in adolescents is 8% to 16%, similar to the 15% prevalence rates in adults (Akbay et al., 2000; Kumanov et al., 2008; Niedzielski et al., 1997; Skoog et al., 1997; Stavropoulos et al., 2002; Zampieri and Cervellione, 2008). Thus the group of adolescents identified as having a varicocele is presumed to be the same group identified as adults, because varicoceles are not known to resolve spontaneously and rarely manifest in older adults.

The frequency and severity of varicoceles vary with age, method of diagnosis, and Tanner development stage. Most varicoceles appear after 10 years of age, progress through puberty, and peak at Tanner stage 3 (Kumanov et al., 2008). Although historically varicoceles were predominantly left sided, recent reports indicate that identification of right-sided varicoceles in boys is increasing. Bilateral palpable varicoceles were repaired in one-third of 10- to 24-year-old males by Decastro et al. (2009), and CDUS identified subclinical left or bilateral varicoceles in 7% to 17% of cases (Akbay et al., 2000; Cervellione et al., 2008; Pfeiffer et al., 2006). Woldu et al. (2013) identified retrograde blood flow in the right side of 40.3% of 503 adolescents with palpable left-sided varicoceles, of which 44% were subclinical. The clinical implication of these subclinical right-sided varicoceles is unclear. In adults, bilaterality is reported in 15% to 50% of cases (Zini and Boman, 2009).

The pathophysiology of the adolescent varicocele is likely to be multifactorial. **The primary factors are believed to be increased venous pressure in the left renal vein, collateral venous anastomoses, and valvular incompetence of the left internal spermatic vein at its junction with the left renal vein.** Varicocele progression may be related to continuous or spontaneous rather than Valsalva-induced spermatic venous reflux (Cervellione et al., 2008; Pfeiffer et al., 2006; Zampieri and Cervellione, 2008). The “nutcracker phenomenon” (compression of the left renal vein between the aorta and superior mesenteric artery) may account for the varicocele in some boys (Coolsaet, 1980; Kim et al., 2006). The reports by Sakamoto and Ogawa of higher peak and antegrade flow and venous diameter in the prostatic venous plexus of men with bilateral varicoceles versus controls and men with unilateral varicoceles (Sakamoto and Ogawa, 2008) and those showing increased risk of saphenofemoral junction incompetence (Karadeniz-Bilgili et al., 2003) and varicose veins (Kilic et al., 2007) reflect a more generalized venous abnormality. Vanlangenhove et al. (2015) compared venographic information between adults and adolescents with left varicoceles and found reflux in adults to be induced via collateral pathways, whereas in adolescents congenital venous abnormalities such as fewer competent valves and more instances of nutcracker phenomenon were more common. Genetic factors may contribute to the risk; the presence of a varicocele was fourfold to eightfold higher among first-degree relatives of men undergoing vasectomy or male kidney donors, and the incidence was especially high in brothers (Mokhtari et al., 2008; Raman et al., 2005). **A tall, thin body habitus (low body mass index [BMI]) is associated with varicoceles in adolescents and adults internationally** (Bae et al., 2014; Handel et al., 2006; Kumanov et al., 2008; Liu et al., 2017; May et al., 2006b; Nielsen et al., 2006; Tsao et al., 2009), perhaps because of increased spermatic vein length and/or hydrostatic pressure, or perhaps resulting from difficulty in identification during physical examination.

Diagnosis and Classification

The majority of varicoceles in children and adolescents are **identified incidentally** by a primary care practitioner or by the patient on self-examination. Less commonly (2% to 11%), adolescents have concerns regarding discomfort (Zampieri et al., 2008a).

The patient should be examined in the supine and standing positions. The scrotum is inspected for visible swelling, followed by palpation of the spermatic cord at rest and during the Valsalva maneuver. The clinical grading system defines varicoceles as *grade 0* (subclinical): nonpalpable and visualized only by CDUS; *grade 1:* palpable only with Valsalva maneuver; *grade 2:* easily palpable but not visible; and *grade 3:* easily visible. **The veins should decompress in the supine position;** failure to do so, particularly on the right side, warrants evaluation (CT or sonogram) for an abdominal or pelvic mass (Roy et al., 1989). Testicular consistency should be assessed; the affected testis may be soft. **Measurement of testicular volume is important because it may predicate surgical intervention.** The volumes should be assessed based on Tanner stage (Table 44.4). Volume can be determined using the Prader orchidometer (chain of 12 solid wooden ellipsoids of increasing volumes that are visually compared with the size of each testis), the Takihara orchidometer (15 elliptical rings with inner dimensions corresponding to ellipsoid volumes placed over the widest testis circumference), or by ultrasound (measure length, width, and depth and use one of several formulas). All three techniques are reliable, but **ultrasound is more sensitive in determining differences in left and right testicular size** (Chipkevitch et al., 1996; Costabile et al., 1992; Diamond et al., 2000). In a canine study, the use of ultrasound and the Lambert formula provided the most accurate and precise testicular volume estimates (Paltiel et al., 2002).

TABLE 44.4

Testicular Volumes Based on Tanner Stage

TANNER STAGE	DANIEL ET AL., 1982				ZACHMANN ET AL., 1974	
	LEFT TESTIS (cm^3)		RIGHT TESTIS (cm^3)		TOTAL (mL)	
	MEAN	SD	MEAN	SD	MEAN	SD
1	4.8	2.8	5.2	3.9	6.0	2.6
2	6.4	3.2	7.1	3.9	6.8	3.6
3	14.6	6.5	14.8	6.1	9.3	3.8
4	19.8	6.2	20.4	6.8	12.6	4.2
5	28.3	8.5	30.2	9.6	16.3	4.6
6					18.9	4.0

SD, Standard deviation.

The ultrasound criteria for diagnosing a varicocele—spermatic vein diameter and retrograde blood flow—are controversial in adults and more so in adolescents. Niedzielski et al. (1997) measured spermatic vein diameter in the standing position and spermatic venous reflux with Valsalva maneuvers in 625 boys with varicoceles and 50 normal controls. They found normal spermatic vein diameter (<2 mm in normal boys) in 95%, 70%, and 4% of boys with grades 1, 2, and 3 varicocele and spermatic venous blood reflux in two-thirds of boys with grade 2 or 3 varicoceles; flow velocity measured while the patient was standing correlated with varicocele grade and sperm motility. Kozakowski et al. (2009) found that spermatic venous diameter measured in the supine position was a poor criterion for clinical varicocele and did not predict risk of testicular volume loss but that peak retrograde spermatic vein flow with Valsalva maneuvers that exceeded 38 cm/sec strongly correlated with testicular volume asymmetry.

Associated Pathological Processes

There is abundant evidence that a varicocele may alter testicular growth, spermatogenesis, and fertility potential. The cause of testicular injury is presumed to be related to increased scrotal temperature, but the pathogenesis remains poorly understood.

Key Points: Varicocele

- The prevalence of varicoceles in adolescent and adult men is similar, approximately 15%.
- Tall, thin males more commonly have varicoceles, implicating a genetic predisposition.
- Varicoceles are commonly identified on examination and least commonly identified as a result of pain.
- Testicular volume is best measured using ultrasound.
- Testicular hypotrophy of 15% to 20% may arise in the presence of an ipsilateral varicocele that commonly resolves after varicocele repair but can resolve spontaneously as well.
- Trends toward poorer sperm quality may be limited to a subset of affected males with varicocele, but grade and postoperative testicular catch-up growth do not reliably predict ultimate semen quality.
- Surgical success rates are similar with retroperitoneal (open or laparoscopic) or subinguinal approaches. Lymphatic sparing techniques offer the lowest rates of hydrocele formation. The majority of hydroceles require surgical intervention.

Testicular Hypotrophy

In the absence of sufficient direct insight into the potential for subfertility (i.e., semen analysis) associated with varicoceles in adolescents, most attention has been on testicular hypotrophy as a surrogate of pathology and indirect marker surgical success. **A decrease in testicular volume has long been associated with varicoceles** (Lipshultz and Corriere, 1977). Steeno et al. (1976) confirmed the finding in adolescents with grade 2 (34.4% had decreased volume) and 3 (81.2% had decreased volume) varicoceles. The correlation between varicocele grade and left testicular hypotrophy has been confirmed in some studies (Thomas and Elder, 2002; Zampieri et al., 2008b) but not others (Alukal et al., 2005; Kolon et al., 2008). Because ipsilateral volume loss may improve or resolve after varicocele repair, it was inferred that hypotrophy reflects significant testicular injury (Kass and Belman, 1987; Lyon et al., 1982). The global impact, and by extension damage, of varicocele was noted by Kass et al. (2001), who found significantly reduced right testicular size compared with control values in Tanner stage 4 or 5 boys with grade 3 left varicoceles. Okuyama et al. (1988) reported right testicular hypotrophy in 22% of patients with grade 2 or 3 left varicoceles, and lower sperm densities among those with bilaterally small testes. Mean right testicular volume increased significantly after left varicocele repair but not in untreated control groups in several other studies (Laven et al., 1992; Paduch and Niedzielski, 1997; Yamamoto et al., 1995).

Significant hypotrophy is variably defined as a 10%, 15%, 20%, or 2- or 3-mL relative difference in testicular size and is found in 10% to 77% of patients (Akbay et al., 2000; Diamond et al., 2004b; Kolon et al., 2008; Lyon et al., 1982; Okuyama et al., 1988; Preston et al., 2008; Thomas and Elder, 2002). This variability is related to the mode of measurement (see following), referral patterns, and the formula used to determine percent differences. Rapid increases in testicular size may occur as early as 10 years of age and persist until age 19, depending on Tanner stage of pubertal development (see Table 44.3) (Daniel et al., 1982; Matsuo et al., 2000; Rundle and Sylvester, 1962; Schonfeld, 1943; Zachmann et al., 1974). Because size variability can vary widely in individuals (Marshall and Tanner, 1970), longitudinal measurements over several years may more accurately define hypotrophy than isolated measurements, particularly in early puberty.

“Catch-up” growth, defined as normalization of left relative to right testicular size, occurs in 32% to 83% of patients after varicocele repair (Barroso et al., 2009; Castagnetti et al., 2008; Cayan et al., 2002; Decastro et al., 2009; Feber and Kass, 2008; Greenfield et al., 2002; Poon et al., 2009; Yaman et al., 2006; Zampieri et al., 2009). The hypothesis that postoperative resolution of left testicular hypotrophy reflects improved testicular function is challenged by observations that testicular size differential may improve spontaneously in untreated patients (Kolon et al., 2008; Paduch and Niedzielski, 1997). In contrast, others report worsening or development of significant hypotrophy in 10% to 26% of boys over time (Kozakowski et al., 2009; Thomas and Elder, 2002; Zampieri and Cervellione, 2008). Finally, Diamond et al. (2004b) reported no statistical difference in either direction in a longitudinal study. Kocvara et al. (2003) posited that lymphatic ligation contributes to increased postoperative testicular volume after lymphatic and arterial ligation, but this was disproved by reports showing no difference in rates of catch-up growth based on lymphatic (Poon et al., 2009) and/or arterial (Barroso et al., 2009) preservation. Laven et al. (1992) noted that varicocele repair increased the volume of small but not normal-sized testes. Postoperative left testicular hypertrophy (>10% size differential relative to the right testis) is attributed to non–lymphatic-sparing procedures or to a rebound effect on spermatogenesis in the affected testis (Cayan et al., 2002; Gershbein et al., 1999; Kocvara et al., 2005).

Significant discrepancy between left and right testicular size remains the primary indication for varicocele correction. Unfortunately, the currently available data are unclear as to the direct relationship between this discrepancy and testicular function with or without correction. **Prospective, randomized studies are needed to clearly establish whether unilateral and/or bilateral testicular hypotrophy or catch-up growth accurately predicts fertility potential in adolescent varicocele.**

Testicular Histology

The histologic effect of varicoceles is better known in adults but is largely absent and inconsistent in adolescents. In adults (reviewed by Hienz et al., 1980), histology findings vary from normal on light and electron microscopy in all men (Fideleff et al., 2000) or even those with severe hypospermatogenesis (Aragona et al., 1994; Kass et al., 1987) to degenerative tubular changes, altered Leydig cell number, and/or proliferative lesions of the vasculature (Hienz et al., 1980). Hadziselimovic et al. (1995) found abnormal tubular maturation and Leydig cell number in a small series of young men who had testicular biopsies at the time of adolescent varicocele repair; these data failed to correlate with ultimate sperm quality in adulthood.

Hormonal Function

The use of hormonal profiles as a proxy to determine if varicoceles are deleterious to testicular function has been inconclusive. Baseline LH and FSH levels are not consistently different in the presence or absence of varicocele in adolescents (Cayan et al., 2005; Ku et al., 2005; Laven et al., 1992; Yamamoto et al., 1995). Basal and stimulated gonadotropin levels were not consistently different in varicocele patients when compared with controls and did not improve after surgery (Fideleff et al., 2000). GnRH stimulation led to an exaggerated LH and FSH response in about 30% of boys with varicoceles but did not correlate with testicular hypotrophy (Kass et al., 1993a). Inhibin B measurements failed to consistently correlate with testicular size or semen parameters in adolescents (Basar et al., 2010; Blevrakis et al., 2016; Carrillo et al., 1999; Romeo et al., 2007; Turkyilmaz et al., 2006). Guarino et al. (2003) observed increased LH, FSH, and simulated FSH levels in 20 boys with varicoceles and abnormal semen parameters compared with 56 with normal semen, but this was confounded by 30% of boys with bilateral varicoceles, a history of inguinal surgery, or cryptorchidism.

Semen Quality

Semen quality is considered the most useful indicator of fertility potential despite many variables associated with collection and interpretation in adolescents. **Progressive improvement in sperm quality may parallel testicular growth and sexual maturation, and so semen analyses may be best obtained at stabilization of testicular growth, which may not depend on age.** In a study of 194 boys aged 12 to 19 years, Janczewski and Bablok (1985a, 1985b, 1985c, 1985d) found that ejaculation began at a bone age of 13 years (within 16 months of the onset of puberty), and normospermia was achieved by a bone age of 17. There were boys at Tanner stage 5 with asthenozoospermia and occasional oligozoospermia. Mean testicular size increased with progression in semen quality but showed a large SD in boys achieving normospermia; LH and FSH levels significantly declined with attainment of normospermia.

Reliable standards for semen quality based on Tanner stage or age do not exist, and therefore recent studies evaluating semen quality among adolescents with varicoceles depend on comparison with adult standards. In the majority of these studies, at least two semen samples were obtained and World Health

Organization criteria were used; however, Tanner stage 5 was not always specified. Christman et al. (2013) recently advocated a single semen analysis, noting sufficient reproducibility of total mobile count (more variability among other parameters) in adolescents at risk for subfertility (varicocele or cryptorchidism). In two randomized studies comparing treated and untreated patients with controls, no differences were found in semen quality at initial or follow-up analysis between groups, except for a significant postoperative increase in sperm concentrations in the treated group (Laven et al., 1992; Yamamoto et al., 1995), hypothesized to be a rebound in spermatogenesis. Correlations between left or total testicular volume and semen parameters were noted by some investigators (Diamond et al., 2007; Haans et al., 1991; Paduch and Niedzielski, 1996) but not others (Guarino et al., 2003). Christman et al. (2014) reported a low total motile count in 48 of 73 patients (66%) followed for 2.7 years (median) by serial scrotal ultrasound evaluating testicular size and semen analysis at Tanner 5, around age 18 years. Testicular volume differential was not predictive of normal semen volume, density, sperm motility, or total motile count, but total testicular volume from the final ultrasound was predictive of total motile count. Kurtz et al. (2015) associated total testis volume and the testicular volume differential with semen analysis outcomes with a testicular volume differential of greater than 20%, doubling the odds of a low total motile sperm count; a total testis volume of less than 30 cc quadruples the odds of a low total motile sperm count.

Investigators were unable to correlate postoperative increases in left testicular volume or varicocele grade with semen analysis data in controlled (Laven et al., 1992) and uncontrolled (Cayan et al., 2002; Diamond et al., 2007; Zampieri and Cervellione, 2008) studies. **The available data suggest that trends toward poorer sperm quality may be limited to a subset of affected males with varicocele, but grade and postoperative testicular catch-up growth do not reliably predict ultimate semen quality.**

Intratesticular Varicocele

In 1% to 2% of adolescents, a varicocele may include an intratesticular component found on CDUS (Diamond et al., 2004a; MacLachlan et al., 2013). The diagnosis is made by identifying venous flow in anechoic structures greater than 2 mm in diameter near the mediastinum testis that increases during Valsalva maneuvers (Bucci et al., 2008). MacLachlan et al. (2013) found worsening testicular asymmetry that responded to surgical correction and progressed in one patient who refused surgery; they concluded that surgery was indicated in adolescents with intratesticular varicoceles and testicular asymmetry.

Treatment

Observation remains the approach of choice for the majority of adolescents with varicocele until a surgical indication is present. **Despite the aforementioned limitations regarding testicular hypotrophy, the main indications for surgical intervention remain significant left (≥20%) or bilateral testicular hypotrophy, pain, or abnormal semen analysis findings; the last is most reliable in boys of Tanner stage 5 and/or at least 18 years of age.** Pain is a rare indication for surgery, reported in only 2% to 10% of patients in most series, and is relieved by the procedure in 68% to 88% of patients (Zampieri et al., 2008a). Despite the aforementioned general principles guiding evaluation and surgical intervention, there is great variability in management approaches in the pediatric urologic community. In separate surveys, Pastuszak et al. (2014) and Coutinho et al. (2014) reported wide variation in intervention indications, preferred surgical approach, follow up, and use of semen analyses. In a survey that specifically assessed the incorporation of semen analysis in practice, Fine et al. (2016) found that only 13% did so routinely. Nearly half had discomfort in addressing the issue with patients and did not order semen analysis.

Surgical Repair of Varicocele

Several approaches exist to correct the adolescent varicocele: inguinal or subinguinal, laparoscopic or retroperitoneal, or venographic. The surgical decision revolves around (1) whether to spare the testicular artery and/or lymphatics using the available approaches and (2) the effect on the rate of recurrence and hydrocele formation (Table 44.5) (Barroso et al., 2009; Castagnetti et al., 2008; Cayan et al., 2005; Diamond et al., 2009; Esposito et al., 2004; Feber and Kass, 2008; Glassberg et al., 2008; Greenfield et al., 2002; Kocvara et al., 2005; Misseri et al., 2001; Poddoubnyi et al., 2000; Schiff et al., 2005; Tong et al., 2009; Yaman et al., 2006). Long-term outcome data are lacking to support any particular approach because the length of postoperative follow-up may be insufficient to identify potential recurrences (Glassberg et al., 2008) or sequelae such as a hydrocele, which may require 2 years or more to develop (Esposito et al., 2004; Feber and Kass, 2008; Misseri et al., 2001).

Whereas many hydroceles may resolve spontaneously, up to one-half may require formal scrotal repair (Diamond et al., 2009; Esposito et al., 2004; Feber and Kass, 2008; Misseri et al., 2001) or aspiration (Esposito et al., 2004) because of large size or symptoms. Yu et al. (2016) demonstrated no difference in improved semen quality when laparoscopic artery sparing and artery ligation techniques were compared.

TABLE 44.5

Results of Adolescent Varicocele Repair

PROCEDURE	RECURRENCE OR PERSISTENCE	HYDROCELE	TESTICULAR ATROPHY
Open suprainguinal (Palomo)	2%–4%	0–30% (10%)[a]	
Laparoscopic:			
Nonlymphatic or artery sparing	0–9%	11%–32% (7%)[a]	
Artery and/or lymphatic sparing	1%–7%	0–4%	
Microscopic subinguinal	0–10%	0–6%	Rare
Nonmicroscopic inguinal	7%–33%	8%–14%	
Sclerotherapy	6%–35%	Occasional	Rare

[a] Number in parentheses refers to meta-analysis of Barroso et al., 2009.

Subinguinal or Inguinal Microsurgical Varicocelectomy

The *subinguinal microscopic approach* provides the advantages of facilitated artery and lymphatic sparing, high rate of success, and low risk of hydrocele but may be time consuming and requires microscopic surgical skills. The procedure used in children is similar to that used in adults as originally published (see Chapter 67). Use of lower degrees of magnification in adolescents (e.g., loupes) may yield inferior results (Cayan et al., 2005; Diamond et al., 2009; Greenfield et al., 2002) than use of an operating microscope. The subinguinal approach is associated in rare cases with testicular atrophy (necrosis), which has not been reported for suprainguinal procedures (Diamond et al., 2009).

Retroperitoneal and Laparoscopic Varicocelectomy

The ligation of the internal spermatic vessels above the level of the internal inguinal ring is a simple procedure performed by open or laparoscopic approaches with high success rates but higher rates of hydrocele formation. Mass ligation, as described by Palomo (1949), offers a highly successful and efficient surgical result. Although potentially more difficult to isolate the arterial and lymphatic vessels, lymphatic- and/or artery-sparing techniques may reduce the incidence of postoperative hydroceles but have an impact on success rate (Kass and Marcol, 1992) and may not benefit catch-up growth (Fast et al., 2014); this was similarly seen in a cohort of adolescents undergoing laparoscopic varicocelectomy (Kim et al., 2014). Zampieri et al. (2007a, 2007b) reported that sparing the artery was associated with improved semen quality; however, randomized prospective data are lacking that clearly define the effect of artery sparing on testicular function. In theory, testis atrophy may follow spermatic artery ligation in patients with prior inguinal surgery (Skoog et al., 1997) but did not occur after laparoscopic Palomo procedures in a small series (Barqawi et al., 2002). Similarly, testis atrophy may occur after non–artery-sparing varicocelectomy and subsequent surgery that compromises the vasal artery or vein (hernia repair, vasectomy).

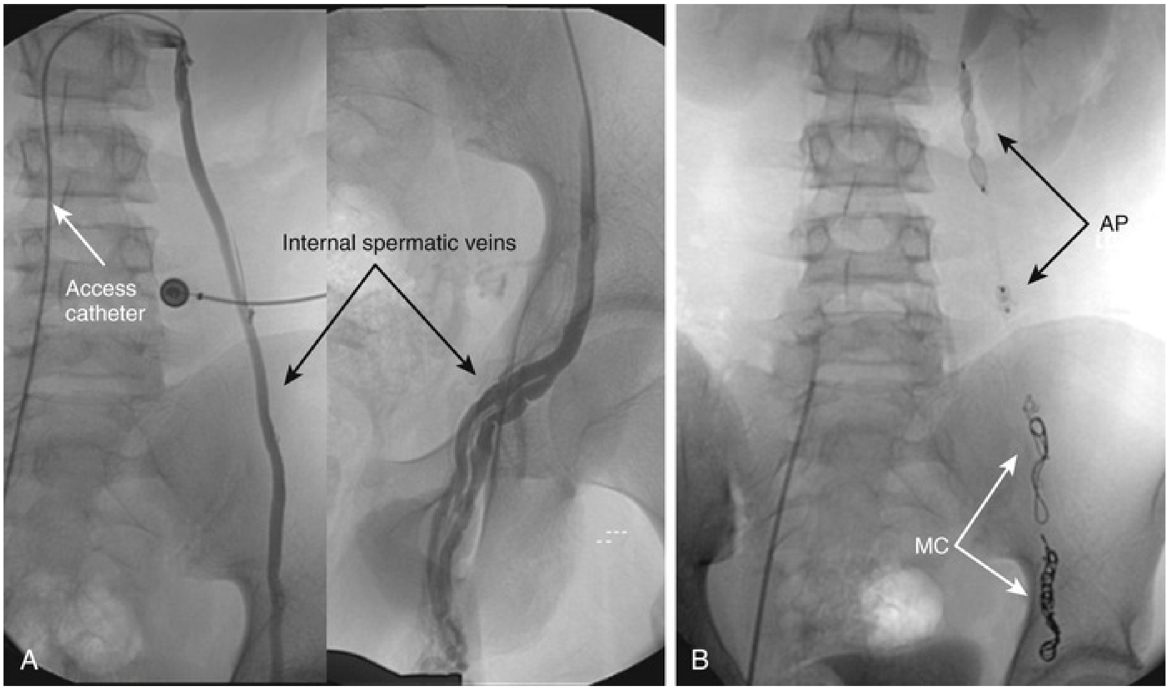
The Palomo open procedure is performed through a muscle-splitting incision medial to the anterior superior iliac spine. The peritoneum is mobilized medially to expose the bundle of spermatic vessels, which are isolated, clipped, or suture ligated and left as such, or the vessels are divided according to surgeon preference. To reduce the risk of postoperative hydrocele formation, a microscopic lymphatic-sparing procedure through this incision was described by Wong et al., without recurrence (Wong et al., 2009), and shown to be faster and more reliable than a subinguinal approach by Silveri et al. (2015).

Laparoscopic varicocele repair is performed using three ports. The two working ports are placed in variable locations: left midclavicular line inferior to the umbilicus and lower midline/right lower quadrant, or both lower quadrants, or both on the right side at the lateral rectus margin. The peritoneum above the internal ring is opened and the vascular bundle and surrounding tissue are mobilized. To help identify the artery, a laparoscopic Doppler probe or papaverine can be used. The magnification provided by the laparoscope helps to identify lymphatic channels as clear tubular structures accompanying the artery and veins (Fig. 44.37). The use of vital dyes injected into the paratesticular tissue to identify lymphatics has potential technical challenges and risks if the dye is inadvertently injected into the testis (Esposito et al., 2014b, Ishibashi et al., 2014; Makari et al., 2007; Schwentner et al., 2006). The vessels may be ligated using permanent sutures or clips and transected using the harmonic scalpel or vessel-sealing devices. To avoid recurrence, vein(s) accompanying the artery should be identified and ligated. Cimador et al. (2008) used CDUS to search for dilated, refluxing deferential veins in the iliac fossa, which were also ligated. Injury to the genitofemoral nerve has been reported in a limited number of adolescent and adult series and may be more commonly associated with use of electrocautery (Muensterer, 2008). This complication manifests as postoperative paresthesias along the proximal anterior thigh that slowly resolve over weeks or months.

(B) Vessels have been isolated and elevated off the posterior abdominal wall. (C) Individual lymphatic channels have been teased out and will be spared and the veins divided. (Courtesy Israel Franco, MD.)

Sclerotherapy or Embolotherapy

The published experience with intravascular injection of sclerosant or thrombotic material to occlude varicoceles in adolescents has been limited and mainly applied to cases of recurrent or persistent varicoceles (eFig. 44.38). The **benefit of this approach is to identify and classify the venous collateralization as possible routes of outflow and reflux.** The agents (3% sodium tetradecyl sulfate or polidocanol, with or without intravascular coils or balloons) can be injected in either a retrograde (Alqahtani et al., 2002; Beutner et al., 2007; Granata et al., 2008; May et al., 2006a; Mazzoni et al., 1999; Reiner et al., 2008; Reyes et al., 1994; Sivanathan and Abernethy, 2003) or antegrade fashion. The benefits of the procedure lie in its minimally invasive approach through a transfemoral venous puncture done under local anesthesia (with or without sedation). However, the procedure has generally inferior success rates compared with surgical (open or laparoscopic) procedures, involves radiation exposure, and cannot be completed for technical reasons in 5% to 22% of cases. The follow-up is short in available literature (rarely more than 1 or 2 years), with recurrence rates of 6% to 35%. Self-limiting complications include pain, epididymo-orchitis, phlebitis, or scrotal swelling; partial testicular atrophy and hydrocele occur rarely. Antegrade techniques entail use of a small subinguinal or upper scrotal incision, isolation of a vein or veins amenable to cannulation with or without fluoroscopic confirmation of antegrade flow into the internal spermatic vein, and injection of a sclerosant followed by ligation of the vein (Carmignani et al., 2009; Zaupa et al., 2006). Success rates are reported to be 4% to 12%, lower than for retrograde sclerotherapy, with similar complications. The venographic information gleaned by the procedure identifies aberrant vasculature in about 25% of cases (Malekzadeh et al., 2016; Wong et al., 2014).



EFIG. 44.38 Antegrade varicocele embolization. (A) The left internal spermatic veins are accessed via the right femoral vein, and venography demonstrates the dilated veins. (B) Postembolization images with two levels of microcoils (MC) and two Amplatzer plugs (AP), representing the typical four levels of embolization. (Courtesy Ardeshir Rastinehad, DO.)

Epididymal and Vasal Anomalies

Congenital anomalies of accessory testicular structures are often associated with primary diseases affecting testicular descent and genital development but may occur as isolated anomalies or as part of syndromes that do not primarily affect the genitalia.

Epididymal cysts are simple cystic structures that may be palpable by the patient or examining physician or found incidentally by ultrasonography (Homayoon et al., 2004). Posey found that over an 8-year period, 14.4% of all boys who underwent scrotal ultrasound had epididymal cyst with increasing incidence with age (35.3% among boys >15 years) (Posey et al., 2010). Epididymal cysts may be clinically indistinguishable from spermatoceles except that the latter occur postpubertally and contain sperm. The pathophysiology of epididymal cysts is unknown but may be related to an altered hormonal environment because they are linked to diethylstilbestrol (DES) exposure (Palmer et al., 2009). These lesions are different ultrasonographically and pathologically from the multicystic, solid epididymal cystadenomas that occur in von Hippel-Lindau disease (Choyke et al., 1997). Homayoon et al. (2004) observed spontaneous resolution of many cysts in their pediatric series, and surgical intervention is rarely needed.

Congenital absence of the vas deferens (CAVD) is in most cases associated with specific mutations of the cystic fibrosis gene *CFTR* (cystic fibrosis transmembrane regulator) that are less severe than those encountered in patients with cystic fibrosis (Kolettis and Sandlow, 2002). The disease can be bilateral (CBAVD) or unilateral (CUAVD) with a normal or obstructed contralateral vas and may be associated with renal agenesis or ectopia and/or partial or complete agenesis of the epididymis and seminal vesicles. *CFTR* mutations are more common in males with CBAVD, and renal anomalies are more common in cases of CUAVD. These patients typically have infertility. Abnormal vasal development may also result in a **persistent mesonephric duct** anomaly that is associated with ipsilateral renal and seminal vesicle agenesis and vasoureteral fusion (Kajbafzadeh and Payabvash, 2006). Reflux into the fused wolffian remnants results in UTI and epididymo-orchitis. Other associated anomalies may include imperforate anus, hypospadias, tracheoesophageal fistula, tetralogy of Fallot, or coarctation of the aorta.

Hypospadias

Christopher J. Long MD, Mark R. Zaontz MD, Douglas A. Canning MD

In 1995 John Duckett, MD, a hypospadias pioneer, wrote: “Hypospadiology requires an in-depth study of the contributions of our predecessors as well as a thorough knowledge of the methods and maneuvers of current experts. To study at a medical center where large numbers of hypospadias cases are managed is more beneficial than the anguish of learning through one's mistakes” (Duckett, 1995). As outlined in this chapter, we have made significant advancements since his passing, but we still have a lot of work to do to improve outcomes. Expanding Dr. Duckett's vision, meticulous documentation, collaboration across multiple centers, and honest outcome reporting will further advance this field.

Embryology

The classic triad of hypospadias, a dorsally hooded foreskin, a proximal urethral meatus, and ventral penile curvature, arises from an arrest in penile development. A more extensive review of penile embryology is covered elsewhere in this volume, so we will focus on the most relevant concepts.

The initial stages of external genital developmental are similar for both sexes. Mesenchymal ingrowth at the cloacal membrane on the ventral surface of the fetus divides it into two halves, forming the foundation for anal and genital anatomy development (Glenister, 1954; Kurzrock et al., 1999). Migrating cells coalesce over the cloacal membrane to form several folds, including the cloacal folds, which merge to form the genital tubercle. The urogenital diaphragm forms below the genital tubercle as the anal and genital systems separate at 7 weeks of gestation. The urogenital folds and the more lateral labioscrotal folds emerge lateral to the urogenital membrane (Fig. 45.1).

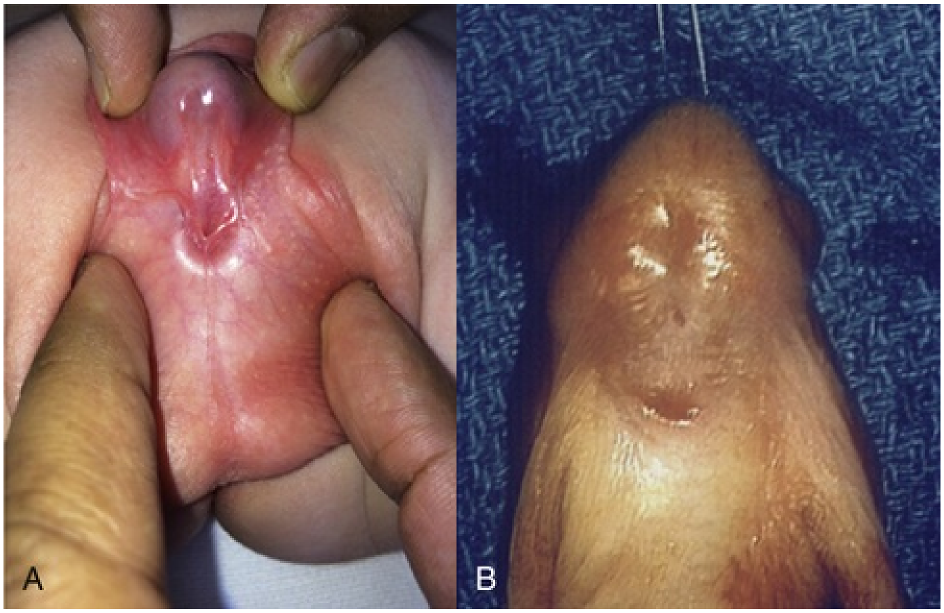
FIG. 45.1 (A) The relationship of the genital tubercle, urogenital fold, urogenital membrane, and labioscrotal swellings in the undifferentiated state of development. (B) In males the urogenital folds fuse while the genital tubercle elongates, forming the penis and glans. The lower image depicts the epithelial invagination theory of distal urethra formation, as opposed to the recently proposed endodermal source for formation of the entire urethra. The labioscrotal folds swell and fuse in the midline to form the scrotum.

The exact mechanism of urethral development is debated. In 1954 Glenister proposed the “ectodermal ingrowth theory,” in which the stratified squamous lining of the glanular urethra originates independently via retrograde ectodermal ingrowth from cannulation of the glans. The glanular urethra then fuses at the coronal margin with the endodermal penile urethral plate, which is forming simultaneously as a result of antegrade fusion of the urethral folds (Glenister, 1954). **This process occurs sequentially from the anus to the distal glans during gestation weeks 8 to 16, the critical period for external genitalia**

development.

Alternatively, recent evidence supports an entirely endodermal origin for the urethra (Kurzrock et al., 1999). **According to this newer theory, the urethral plate formation is contiguous from the penile urethra into the glans and undergoes differentiation to form the stratified squamous layer** (Kurzrock et al., 1999). The authors have further refined their theory on urethral development to describe the two-zipper hypothesis of urethral development. This begins with the “unzipping” event, stemming from proliferation of the flat urethral plate into a canalized urethral groove, which is lined with flanking urethral folds. This process is seen in the male and female urethra. **The “closing zipper” is androgen dependent and unique to the male urethra. As opposed to a simple fusion of the urethral folds, the fusion process occurs in an interlacing fashion at varying rates and levels, forming the contiguous urethra** (Li et al., 2015; Shen et al., 2016). Disruption of this process results in the large spectrum of variants of hypospadias (Fig. 45.2).



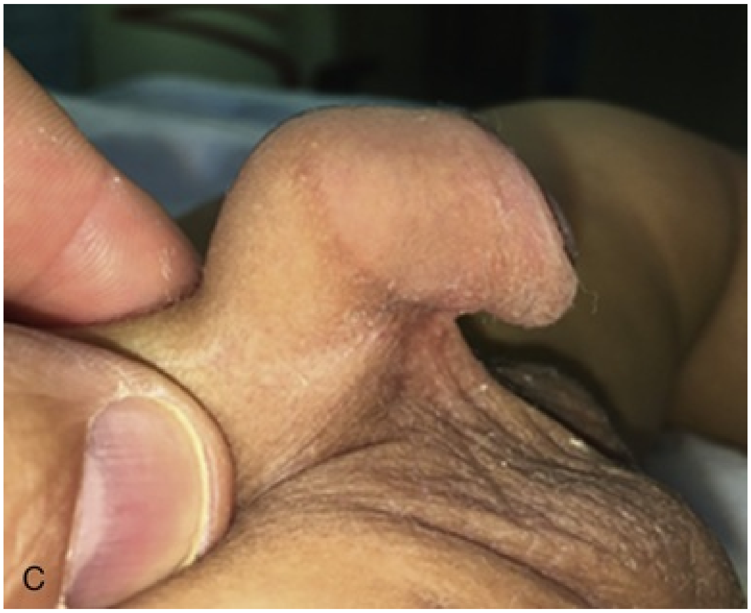


FIG. 45.2 (A) A boy with a proximal hypospadias variant with hypoplastic ventral shaft skin, a penoscrotal meatus, and severe ventral penile curvature. The glans appears small and with a poorly developed groove. (B) A boy who has a subcoronal meatus with a flat glans groove and a lack of ventral foreskin. (C) A boy with severe ventral penile curvature.

Prepuce development coincides with and is dependent on normal urethral development. At approximately 8 weeks of gestation, preputial folds first appear on the distal penile shaft at the base of the corona (Glenister, 1954). These folds first fuse dorsally, then with further penile growth, join ventrally to envelop the developing glans. This process is limited by the developing urethra**. Ventral fusion is not completed until the urethral folds fuse, typically around 20 weeks of gestational age** (Baskin and Ebbers, 2006)**. Therefore incomplete urethral fold fusion results in an ectopic meatus accompanied by incomplete foreskin, seen in 95% of boys with hypospadias** (Baskin and Ebbers, 2006). Contrary to this theory, megameatus with an intact prepuce (MIP) is seen in 5% of cases. The precise cause of this variant, characterized by a widened, distal urethral meatus with a normal foreskin and a lack of severe curvature, is unclear, but we know that complete development and midline fusion of the preputial folds are not always accompanied by an intact urethra (Duckett and Keating, 1989).

External genital development occurs in two phases, a hormone-independent phase and a hormone-dependent stage, beginning at the eighth week of gestation. **Expression of the sex-determining region of *Y* chromosome (SRY) gene product between 7 and 8 weeks of gestation results in masculinization of the**

undifferentiated gonad, testosterone production, regression of female structures, and elongation of the genital tubercle (Baskin and Ebbers, 2006). Leydig cell–produced testosterone is locally converted by 5α-reductase type 2 to dihydrotestosterone (DHT) by cells in the developing external genitalia, further promoting growth (Kim et al., 2002). The growth factor *Sonic Hedgehog (Shh)* plays a critical role in genital tubercle formation and urethral plate formation (Miyagawa et al., 2011). **Androgen receptors have been localized to the penile skin, inner prepuce, urethra, and stromal cells of the corpus spongiosum during the early gestation period, suggesting an equally vital role for androgens in urethral development** (Kim et al., 2002)**. In patients with a lack of androgen receptor stimulation, there is a lack of midline fusion of the scrotal and/or urethral folds, as occurs in female development, which lacks DHT and androgen receptors.**

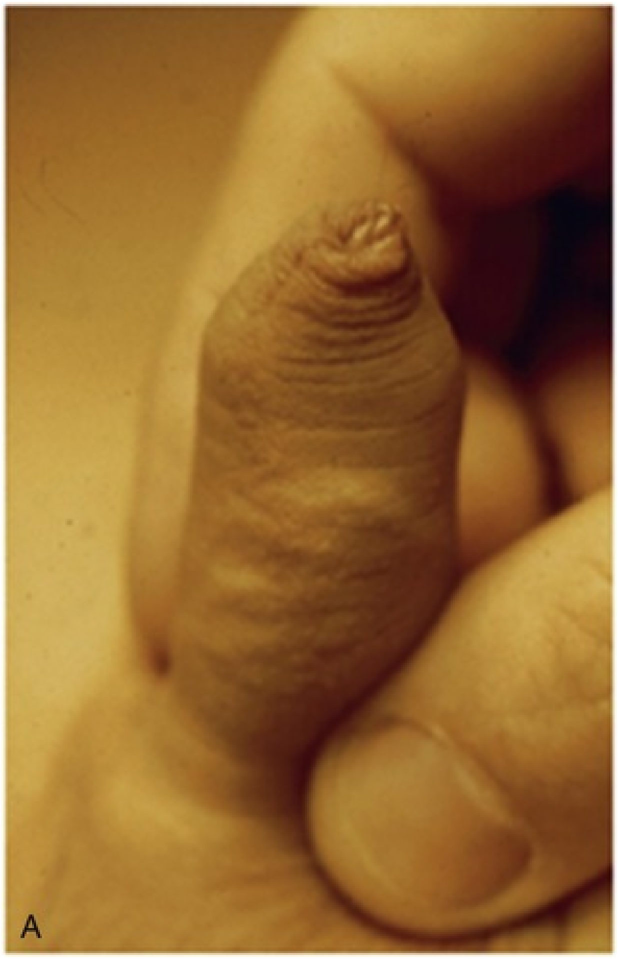
Key Points

- Dihydrotestosterone at the 8- to 12-week gestational phase is a key mediator in the proper development of the penis.
- Male urethra closure is an androgen-dependent process, contrasting its formation to that of the female urethra.

Diagnosis of Hypospadias

Hypospadias is one of the most common congenital anomalies in boys, occurring in 1 in 150 to 300 live births (Elliott et al., 2011; Springer et al., 2015). **Diagnosis is made on physical exam and includes the following three criteria: an ectopic, ventrally located urethral meatus; ventral penile curvature; and an incomplete, dorsally hooded foreskin.** Hypospadias is a broad term, however, and the severity of each component can vary greatly from boy to boy.

The latter two elements are not always present. Up to 5% of boys with hypospadias have an intact prepuce (the previously mentioned MIP variant) and are not diagnosed until the foreskin becomes retractable or reduced at the time of circumcision (Fig. 45.3). Because the intact prepuce can hide the presence of incomplete urethral development in a newborn infant, it is critical to retract the foreskin before circumcision to avoid missing this anomaly and potentially injuring the incomplete urethra or removing foreskin that could be incorporated in an ensuing urethral reconstruction (Hatch et al., 1989). Some have compared the outcomes of patients with a MIP variant for a prior circumcision to no prior circumcision, concluding that prior circumcision did not negatively affect hypospadias repair (Chalmers et al., 2014; Snodgrass and Khavari, 2006). In our experience a circumcision can be performed if the penis is carefully assessed to rule out a more severe variant of hypospadias with either a ventral skin deficiency or ventral penile curvature. In these instances a circumcision should be avoided because it may be necessary to correct these anomalies.



A

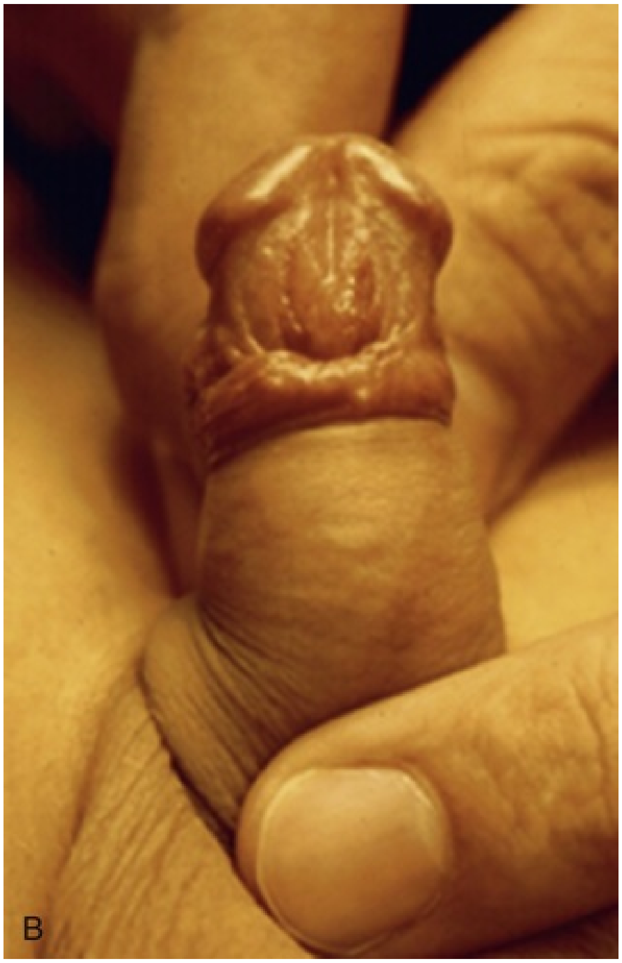


FIG. 45.3 (A) This boy has what appears to be an intact prepuce and normal penis. (B) Once the foreskin is retracted, the hypospadias is obvious. There is separation of the glans wings and a distal penile shaft meatus, representing the megameatus with an intact prepuce (MIP) variant.

Another variant includes boys who have penile curvature without hypospadias. These boys have all the elements of the hypospadias complex but have an orthotopic meatus. In these cases, if circumcision is desired, it should be deferred until definitive surgical management of the curvature can be performed in the operating room because the foreskin may be needed for reconstruction.

The urethral meatus location has classically been used to define severity of hypospadias (Snodgrass et al., 2011). Using this criteria, the majority of boys (70%–85%) have a mild, distal meatus variant (Borer et al., 2001; Duckett, 1989; Pfistermuller et al., 2015; Rushton and Belman, 1998; Fig. 45.4). Proximal hypospadias occurs in 10% to 25% of patients and presents several unique management challenges to the surgeon (Bergman et al., 2015; Manzoni et al., 2004). A classification based solely on the location of the urethral meatus oversimplifies the hypospadias phenotype and may even be misleading. **Boys who have what appears to be a distal urethral meatus may have severe ventral curvature, hypoplastic tissue overlying a more proximal urethral meatus, and a lack of ventral penile shaft skin, increasing the complexity of the repair and the risk of complication (Fig. 45.5).** Thus defining hypospadias complexity simply based upon the location of the urethral meatus underestimates the severity in some boys. **A classification system that includes the location of the urethral meatus as well as the degree of penile curvature after degloving leads to a more definitive and relevant diagnosis.**

Posterior (Proximal)
Perineal

FIG. 45.4 Various potential locations for the ectopic urethral meatus in hypospadias. The classical description was based on the location of the urethral meatus and divided into distal, midshaft, and proximal hypospadias.

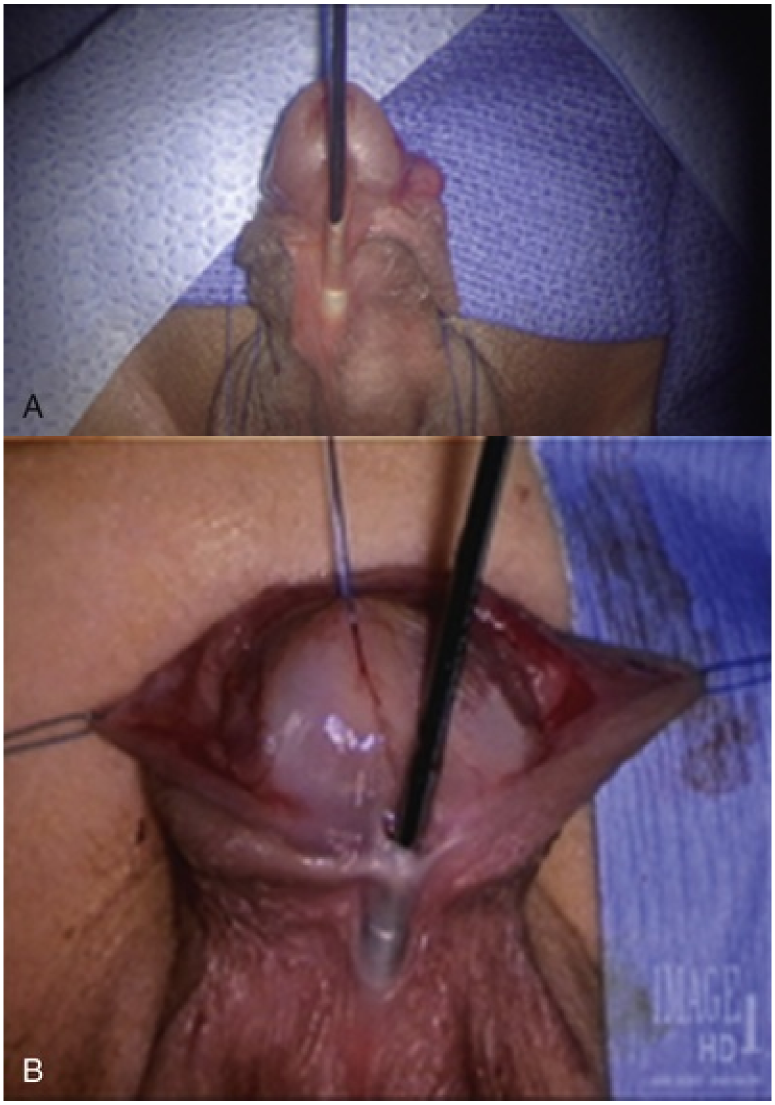

FIG. 45.5 (A and B) Hypospadias classification based solely on the location of the urethral meatus can be deceiving. These two patients have what appears to be a distal hypospadias with a subcoronal meatus, but insertion of a bougie à boule reveals hypoplastic ventral shaft skin and absent corpus spongiosum to the level of the penoscrotal junction. Both of these boys have what we consider to be a severe or proximal hypospadias variant in spite of the initial location of the urethral meatus.

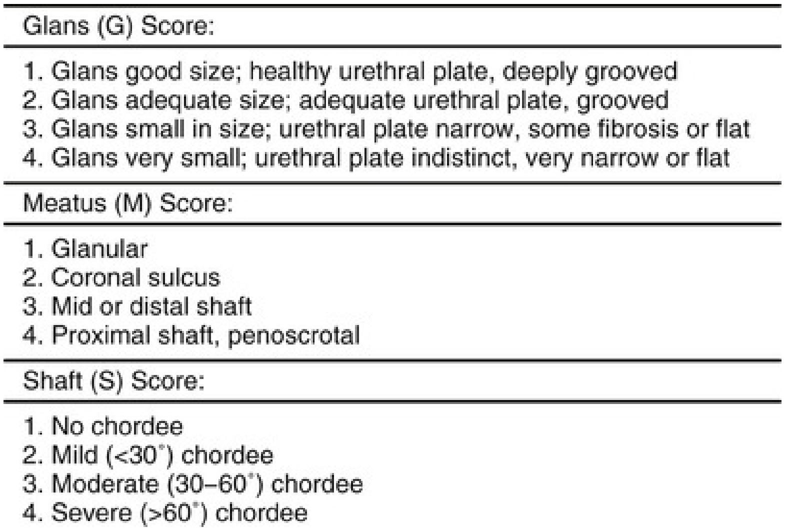
The GMS score (glans meatus and penile shaft [curvature]) incorporates physical exam findings in the operating room, assessing the quality of the glans and urethral plate, the location of the urethral meatus, and the degree of penile curvature, to objectively assign scores to stratify severity (Fig. 45.6; Arlen et al., 2015; Merriman et al., 2013). Indeed, higher GMS scores correlate with an increased risk of developing a complication (Arlen et al., 2015; Merriman et al., 2013). The GMS score assessment was developed for use in the operating room because office measurements have proven to be less accurate at assessing severity, particularly the degree of ventral penile curvature. It remains to be seen whether an office-based exam can provide the same degree of granularity that is obtained in the operating room, but for now the latter remains the gold standard measurement of phenotype severity.



Glans (G) Score:

1. Glans good size; healthy urethral plate, deeply grooved
2. Glans adequate size; adequate urethral plate, grooved
3. Glans small in size; urethral plate narrow, some fibrosis or flat
4. Glans very small; urethral plate indistinct, very narrow or flat

Meatus (M) Score:

1. Glanular
2. Coronal sulcus
3. Mid or distal shaft
4. Proximal shaft, penoscrotal

Shaft (S) Score:

1. No chordee
2. Mild (<30°) chordee
3. Moderate (30–60°) chordee
4. Severe (>60°) chordee

FIG. 45.6 The glans meatus and penile shaft (GMS) score is assessed at the time of the procedure. Each element assigns a higher number score for increasing severity. A small, flatted glans with a poorly defined urethral plate achieves a higher glans score, whereas a proximal location a higher meatus score, and more severe ventral curvature for the shaft score. The components are additive to assign a summary score. (From Merriman LS: The GMS hypospadias score. *J Pediatr Urol* 9:707–712, 2013.)

The initial evaluation of boys with hypospadias requires a careful history and physical examination. In addition to the triad of hypospadias, boys may have associated anomalies, including penile torsion, penoscrotal webbing, and penoscrotal transposition, that must be considered when planning the repair. Physical examination may note dysplastic ventral tissue in boys with hypospadias. Ventral curvature from lack of ventral shaft skin may be immediately obvious on exam. Anatomic studies have shown worsened curvature and shorter penile length in boys with proximal hypospadias. Ultrasonic elastography studies have found less elastic tissue and androgen resistance in boys with proximal hypospadias, suggesting more dysplastic tissue, which not only causes penile curvature but can also complicate surgical reconstruction (Bush et al., 2013a; Camoglio et al., 2016; Snodgrass et al., 2014a).

The most common anomalies associated with hypospadias are inguinal hernia and/or hydrocele and cryptorchidism. Inguinal hernia and/or hydrocele is more common, ranging from 9% to 16%, but no increased incidence is noted with severity of hypospadias (Wu et al., 2002). **Cryptorchidism is found in approximately 7% of patients with hypospadias. This increases to nearly 10% with more proximal hypospadias** (Hjertkvist et al., 1989; John Radcliffe Hospital Cryptorchidism Study Group, 1992; Shima et al., 1979; Sorber et al., 1997; Weidner et al., 1999; Wu et al., 2002). **The AUA cryptorchidism guideline recommends that all boys with unilateral or bilateral undescended testes and severe proximal hypospadias must undergo additional testing to rule out a disorder of sexual differentiation (DSD), which occurs much more frequently in these settings** (Kaefer et al., 1999; Kolon et al., 2014; Moreno-Garcia and Miranda, 2002; Rajfer and Walsh, 1976; Rohatgi et al., 1987).

Guidelines introduced in 2006 included severe hypospadias as a form of 46,XY DSD (Hughes et al., 2006). The concern for DSD is particularly high in a boy with hypospadias and a nonpalpable testis. Kaefer et al. (1999) examined 79 patients with a history of hypospadias and cryptorchidism. **Those with a nonpalpable testis(es), either unilateral or bilateral, had a threefold increased risk for having an underlying DSD diagnosis identified (approximately 50% vs. 15%). There was a significantly increased risk of DSD with proximal hypospadias compared with distal hypospadias (64% vs. 7%)** (Kaefer et al., 1999). A normal 46,XY karyotype may be misleading, particularly in boys with the most severe variants. The surgeon must be alert for contributing diagnoses such as 5α-reductase deficiency, androgen receptor insensitivity, decreased testosterone production associated with testicular dysgenesis, and ovotesticular DSD. Workup may include ultrasound (to rule out müllerian remnants), karyotype, and hormonal analysis (testosterone, FSH, LH, AMH). **These data remind surgeons to look carefully for signs of DSD when planning surgery in a boy with proximal hypospadias.**

Key Points

- Hypospadias is diagnosed by physical exam and includes the following three criteria: an ectopic, ventrally located urethral meatus; ventral penile curvature; and an incomplete, dorsally hooded foreskin.

- The classic definition of hypospadias severity focused on the location of the urethral meatus. A classification system that includes the location of the urethral meatus as well as the degree of penile curvature after degloving leads to a more definitive and relevant diagnosis.
- The presence of hypospadias and unilateral or bilateral cryptorchidism should raise concern for a DSD and prompt an appropriate workup.

Etiology of Hypospadias

Hypospadias is multifactorial in origin, including genetic and environmental concerns. Risk factors include premature birth, infants small for gestational age (<10th percentile for weight, length, and/or head circumference), and intrauterine growth restriction. All have been associated with an increased risk for having a newborn with hypospadias (Gatti et al., 2001; Ghirri et al., 2009; Hussain et al., 2002). In particular there is a trend toward premature birth (<37 weeks) and low birth weight in those with a combination of proximal hypospadias and cryptorchidism (Sekaran et al., 2013). One theory to explain this finding is placental insufficiency, which frequently contributes to small-for-gestational-age boys. Decreased placental weight at birth is associated with a twofold increase in hypospadias development and a 1.5 times risk of cryptorchidism (Arendt et al., 2016). Use of assisted reproduction techniques are also associated with higher rates of hypospadias (Wennerholm et al., 2000). Although these infants also have higher rates of prematurity, low birth weight, and twinning, multivariate analysis suggests that assisted reproduction remains an independent factor (Funke et al., 2010).

Epidemiologic analysis has identified strong familial associations of hypospadias, suggesting a genetic component (Fredell et al., 2002; Schnack et al., 2008). **Studies of twin boys reveal a concordance rate of 9% to 27% in a twin brother, whereas an affected boy has a 9% to 15% chance of having a first-degree relative with hypospadias (brother, father)** (Asklund et al., 2007; Bauer et al., 1979). A nationwide Danish registry of more than 1 million boys identified 5380 boys with hypospadias, implicating maternal and paternal transmission and found an elevated risk for even third-degree relatives (Schnack et al., 2008).

In spite of these findings, attempts at elucidating a “one-hit” gene mutation for sporadic hypospadias have been disappointing, because discrete chromosomal abnormalities are found in only up to 30% of boys with hypospadias (Bouty et al., 2015). Detailed review of the genetic basis of hypospadias is beyond the scope of this chapter but warrants review (Bouty et al., 2015; Kalfa et al., 2011). Various genes have been implicated and segregating them into broader categories is feasible. Homeobox genes (HOX) and fibroblast growth factor (FGF) have been identified as important members of the cascade for penile development. Wilms tumor 1, SOX9, DMRT1, and GATA4 affect gonad development and have been associated with hypospadias. **Finally, mutations within the androgen cascade, androgen production and reception, have been implicated. These include all elements of androgen production, including the luteinizing hormone (LH) receptor gene, 5α-reductase gene, the androgen receptor, and normal testicular development** (Baskin et al., 2001; Fredell et al., 2002; Silver and Russell, 1999).

Nearly 200 syndromes with known genetic causes have an associated hypospadias, although these represent a fraction of those boys with idiopathic forms (Kalfa et al., 2011). The most commonly encountered associations include WAGR (Wilms tumor [WT]), Aniridia genitourinary abnormalities, and developmental delay [R]), Denys-Drash syndrome (genitourinary malformations, renal failure, and high risk for WT), and Smith-Lemli-Opitz syndrome (malformations of the heart, lungs, kidneys, gastrointestinal tract, and genitalia) (Bouty et al., 2015).

Since the 1970s, several large population studies across the world have reported rising rates of hypospadias, some as high as 3% per year (Chul Kim et al., 2011; Lund et al., 2009; Paulozzi, 1999; Toppari et al., 2010). Others have disputed this trend, reporting stable incidence and explaining perceived increased rates reported by others as increased reporting of more mild variants (Bergman et al., 2015; Lane et al., 2017). On the other hand, a study in Sweden over a 40-year period reported a rising trend in incidence for distal and proximal variants (Nordenvall et al., 2014). **Taken together, these data suggest the rate is either stable or increasing. This fact, combined with concerns for a concurrent rise in the rate of cryptorchidism and a decrease in sperm quality, has created concern for a common cause, likely an environmental source, to explain these genital-specific findings**.

The testicular dysgenesis syndrome (TDS) hypothesizes that this series of increasingly frequent male reproductive developmental disorders, including poor semen quality, increased risk of testicular cancer, cryptorchidism, and hypospadias, are secondary to a fetal exposure that directly affects the androgen cascade and genital development (Skakkebaek et al., 2001). This constellation is thought to be multifactorial in origin and includes environmental and genetic insults resulting in testicular dysgenesis, originated from abnormal testicular development in utero (Skakkebaek et al., 2001). **Animal studies have identified a direct correlation between pesticide exposure, disruption of the androgen cascade, and abnormal genital development** (Gray and Kelce, 1996; Hayes et al., 2002; Toppari et al., 1996). Potential causative agents under investigation include pesticides (exposure in the workplace and in foods with elevated levels of pesticides), hormones (birth control medication, diethylstilbestrol [DES]), phthalates (found in plastics and hairspray), and phytoestrogens consumed in a vegetarian diet (Baskin et al., 2001; Kalfa et al., 2015). These environmental disrupting chemicals (EDC), in theory, competitively inhibit androgen receptor binding and disrupt external genital development, although efforts at establishing a link in humans have been unsuccessful (Baskin et al., 2001; Gaspari et al., 2012; Toppari et al., 1996). In a study performed in southern France, after removing patients with hypospadias and age-matched controls, the authors were able to identify a significant risk for developing hypospadias after parental exposure to EDC, specifically detergents, pesticides, and cosmetics, during pregnancy. The authors found an increased risk for environmental exposure alone, but this risk was higher when combined with occupational exposures (Kalfa et al., 2015). Because these chemicals are ubiquitous, it is challenging to avoid them to study them in isolation. Nevertheless, understanding their role in hypospadias development is vital.

The anogenital distance (AGD) is measured from the center of the anus to the most caudad midline border of the penoscrotal junction. **This distance, which is thought to be a measure of disrupted genital development, is shorter in boys with suspected exposure to EDC** (Swan et al., 2005)**. Corroborating reports in animal models, shorter AGD in males has been associated with infertility, cryptorchidism, and hypospadias. In addition, shorter AGD is directly proportional to hypospadias severity** (Cox et al., 2017; Eisenberg et al., 2011; Hsieh et al., 2012; Jain and Singal, 2013).

Key Points

- There is an increased risk of hypospadias in births resulting from assisted reproduction and monozygotic twins.
- The cause of hypospadias is multifactorial, but placental insufficiency and androgen disruption, in part via environmental exposures, are potential culprits in what is thought to be an increasing rate of hypospadias development. Anogenital distance is a reflection of disruption of this cascade and may correlate with phenotype severity.

Surgical Assessment

The goals of surgical reconstruction in boys with hypospadias include correction of penile curvature to ensure a long, straight erection, advancement of the urethra to ensure normal passage of urine and semen through the glans, and the creation of a cosmetically pleasing penis. The surgeon must assess the potential long-term significance of the defect and have an objective discussion with the boy's parents as to whether a surgical repair should be performed. In some cases, in which the penis is straight while erect and the urethral meatus is distal enough to allow for urination while standing, there may be limited benefit to a repair. Repair should be accomplished with the minimum number of procedures to ensure an adequate long-term result, extending into adulthood. **Achievement of this goal includes preparation of the family and patient for the proper procedure, accurate anatomic assessment, and an honest discussion about surgical outcomes and potential complications.**

Surgical timing is important. The timing of the repair should balance the potential adverse psychological effects of surgery, the anesthetic risk to the child, the degree of penile development that will facilitate a successful repair, and wound healing differences as boys age (Bermudez et al., 2011). Genital awareness begins to occur around 18 months of age and progresses with advancing age (Schultz et al., 1983). Boys undergoing earlier repair (usually before 12 months of age) experienced less anxiety and have improved psychosexual outcomes compared with boys undergoing repair at older ages (Belman and Kass, 1982; Perlmutter et al., 2006). Boys operated on at a younger ages may also experience fewer complications, a finding that reinforces the need for early correction (Perlmutter et al., 2006). Comparatively speaking, hypospadias surgery in adults may be associated with a higher complication rate (Hensle et al., 2001). **Based on these studies, in 1996 the American Academy of Pediatrics Section on Urology recommended that elective hypospadias repairs occur between the ages of 6 and 12 months, within which a few exceptions remain in our practice today** (American Academy of Pediatrics, 1996).

Parents frequently ask about the safety of anesthesia when contemplating surgery in their infant son. Data in animals suggest varying degrees of neurotoxicity in response to agents used for general anesthesia (Jevtovic-

Todorovic et al., 2003). Because studies that include brain biopsies in animals are impossible to replicate in human subjects, we must rely on longitudinal observational studies in children. Children exposed to anesthesia (general vs. regional block) for hernia repair had no detectable neurodevelopmental delays at 2 years of age (Davidson et al., 2016). Although research continues, based on current evidence it appears that there are few consequences after a single anesthesia exposure with short-term follow-up (Sun et al., 2016). As additional clinical studies are completed, we will have more information with which to counsel families (Pinyavat et al., 2016). **As a result, the preoperative surgical consultation with the boy's parents must include a careful assessment of the benefits of a surgical repair versus an age-based discussion of the risk of general anesthesia.**

The initial evaluation of boys with hypospadias requires a careful history and physical examination. A focused history should identify prior surgeries (such as circumcision, bladder, or scrotal or hypospadias surgery), urinary tract infections (UTIs), voiding dysfunction, the presence of penile curvature with erection, and any associated medical diseases that may complicate care, such as asthma or a bleeding diatheses. Physical exam should include a measurement of penile length and careful groin examination to assess for undescended testis on either side. Assessment of anogenital distance may also prompt a workup for androgen insensitivity, which could have implications during puberty.

Routine radiographic assessment with voiding cystourethrogram (VCUG) or renal bladder ultrasound (RBUS) in patients with hypospadias is not recommended. In a systematic analysis, the most common associated anomalies included vesicoureteral reflux (VUR), hydronephrosis, and renal position anomalies. These studies were done before the era of routine fetal imaging and the findings were of minimal clinical significance (Chariatte et al., 2013). Boys with a history of other global systemic anomalies should be considered for evaluation with a screening RBUS for the presence of associated urinary tract abnormalities (Khuri et al., 1981). A prostatic utricle may be present, more commonly in boys with proximal hypospadias, and may pose a risk for voiding dysfunction or UTI because of urine entrapment and stasis after the repair (Devine et al., 1980). Surgeons may consider cystoscopy and removal of the utricle at the time of the repair, but the fact that the majority of boys with utricles are asymptomatic and the high risk for injury to the vas deferens make this a rare indication for intervention (Hester and Kogan, 2017).

The preoperative physical examination should assess severity, which will guide surgical planning. The assessment includes the degree of penile curvature, the location of the urethral meatus, the quality of the urethral plate, and the quality of penile skin for reconstruction (Merriman et al., 2013). **Although it is difficult to precisely determine the severity of the phenotype before surgery, particularly the location of the meatus and degree of penile curvature, the surgeon should try to assess the need for a two-stage repair, which is best discussed with the family before the day of surgery** (Snodgrass et al., 2011). If hypospadias is encountered at the time of newborn circumcision, careful evaluation of the severity should be performed and circumcision aborted if there is curvature or skin deficiency. As discussed earlier, boys with unilateral or bilateral undescended testes, perineal hypospadias, or ambiguous genitalia must undergo additional workup to rule out a disorder of sexual differentiation, which occurs much more frequently in this setting (Kaefer et al., 1999; Moreno-Garcia and Miranda, 2002; Rajfer and Walsh, 1976; Rohatgi et al., 1987).

Preoperative Androgen Stimulation

The use of preoperative androgen stimulation in hypospadias surgery is controversial. Bush et al. (2015) reported that a small glans size (defined as a width of less than 14 mm) at the time of surgical repair has been associated with increased risk for complications. Although this group and others have since questioned the importance of glans width and attributed higher complications to technical errors, many surgeons remain concerned that urethroplasty in boys with a small glans results in more complications (Faasse et al., 2016). **Preoperative androgen stimulation, in the form of DHT, human chorionic gonadotrophin (hCG), or testosterone, can be used in prepubertal boys to increase the size of the glans and the penis** (Asgari et al., 2015; Gearhart and Jeffs, 1987; Luo et al., 2003; Nerli et al., 2009)**. Increasing glans size is thought to decrease the amount of tension on the glansplasty and increase the amount of tissue available for urethroplasty, potentially decreasing the complication rate**.

Concerns for androgen stimulation in these boys include aggressive behavior, increased erections, skin discoloration, and secondary male characteristics, all of which are transient and resolve spontaneously within 6 months after the last dose (Asgari et al., 2015; Paiva et al., 2016). Some surgeons prefer to avoid preoperative testosterone because of a perceived increased risk for bleeding as a result of increased angiogenesis. Others believe that poor wound healing may follow androgen exposure (Ashcroft and Mills, 2002; Gilliver et al., 2009). Therefore androgen use is controversial (Gorduza et al., 2011; Menon et al., 2017). To complicate the discussion further, variable degrees of androgen insensitivity may be present in boys with severe proximal hypospadias, which may lead to abbreviated response to androgen stimulation (Snodgrass et al., 2014a).

Several meta-analyses and systemic analyses have been performed in an attempt to answer the question as to whether androgen stimulation reduces or increases the complication rate (Kaya et al., 2008; Netto et al., 2013; Wong and Braga, 2015). Unfortunately, the reported data are variable, specifically the mode of administration, severity of hypospadias, and lack of standardized outcome assessment, precluding meaningful conclusion. Two recent randomized trials have reported fewer complications after preoperative testosterone administration (Asgari et al., 2015; Kaya et al., 2008). A survey of pediatric urologists suggests that preoperative androgen therapy was common before hypospadias repair in boys with proximal hypospadias or in those with a small glans (Malik and Liu, 2014). We use testosterone in some boys, particularly if the glans is small. If we use it, we administer preoperative testosterone cypionate intramuscularly (IM) 5 and 2 weeks before the planned surgery date to boys with a glans width of less than 15 mm. We feel as though the IM route of administration achieves a more consistent increase in glans width and is tolerated well by children.

Intraoperative Assessment and Management

Use of a regional anesthetic is an important feature of a balanced anesthetic in boys undergoing repair for hypospadias. Regional blockade, with either a caudal or circumferential penile block, reduces narcotic requirement during the procedure and improves pain control in the immediate postoperative period (Morrison et al., 2014; Soliman et al., 1978). A survey of practicing urologists found that regional blocks are commonly used in hypospadias surgery, with more urologists preferring a caudal block (Kim et al., 2016). For longer procedures, a second caudal dose can be administered before concluding the case to prolong the analgesic effect in the postoperative period (Chhibber et al., 1997; Samuel et al., 2002). Recently, use of a pudendal nerve block has emerged as an alternative method of regional blockade. The benefits of the pudendal block include a wider coverage area than a penile block, including the ventral penis, perineum, and scrotum. It also reduces the risk of the potential side effects of a caudal block, such as lower extremity weakness, which makes the use of a caudal block less attractive in older children (Kendigelen et al., 2016). In addition, ketorolac (0.5 mg/kg IV), given as a single dose 30 minutes before the conclusion of the procedure, can be an effective adjunctive analgesic, depending upon the surgeon's comfort level with the concern for postoperative bleeding (Morrison et al., 2014; Watcha et al., 1992).

Recent groups have released conflicting reports regarding the secondary effects of caudal anesthesia and surgical hypospadias repair. Kundra et al. (2012) noted a higher rate of fistula formation in boys who underwent caudal compared with penile block (19.2% vs. 0, $P < .001$). **They documented a 27% increase in penile volume 10 minutes after the caudal was placed, theorizing that the penile engorgement leads to increased swelling and compromised wound healing. These authors also found penile block to provide better pain control after distal hypospadias repair. Other single-institution studies have confirmed similar concerns for an increased complication development when a caudal block is administered** (Kim et al., 2016; Saavedra-Belaunde et al., 2017; Taicher et al., 2017). On the other hand, others have found no association between caudal blockade and complications after hypospadias repair (Braga et al., 2017; Zaidi et al., 2015). **Both papers that refute the association between complications and caudal anesthesia believe that boys undergoing caudal had more severe forms of hypospadias and therefore higher complication rates. All of these reports are limited by marginal statistical power, randomization, and patient numbers, leaving the question of an increased complication risk with caudal use unanswered.** We still routinely use caudal blocks for hypospadias repair.

Surgical planning continues after the induction of anesthesia. After antiseptic preparation and administration of intravenous antibiotics, the genitalia are carefully examined to determine surgical approach. We do not perform routine cystoscopy except in cases of severe proximal hypospadias or reoperative procedures. Prostatic utricles, if present, can make catheter placement difficult. Utricles occur more frequently in proximal hypospadias. If a large utricle is suspected, because of severity of the hypospadias or from prior imaging, a cystoscopic examination may be useful to prepare for a more complicated catheter placement (Ciftci et al., 1999).

Preoperative assessment of the hypospadias should proceed as follows. With the boy asleep the preputial glanular adhesions are released and the location of the urethral meatus, quality of ventral shaft tissue, and degree of penile curvature are assessed. Sometimes a proximal hypospadias masquerades as a distal hypospadias with severe penile curvature and a hypoplastic ventral shaft skin (see Fig. 45.5). The surgeon must recognize this before incision to ensure that the appropriate repair is performed. A circumscribing incision is then made and the penis is degloved, partially or completely, depending upon the degree of penile curvature. Care should be taken to develop a mucosal collar, rotating inner shiny preputial tissue from dorsolateral skin to the ventrum where it is lacking. This will aid in ventral shaft skin coverage and yield an improved cosmetic result (Firlit, 1987).

Key Points

- The goals of hypospadias reconstruction include achievement of a straight phallus with proper urinary and sexual function, as well as a cosmetically pleasing appearance.
- The conversation about the risk of hypospadias repair should include the risks of early anesthesia exposure versus the benefits of surgery at a younger age.
- Routine preoperative imaging is not recommended in boys with nonsyndromic hypospadias.
- Preoperative androgen stimulation can transiently increase the penile length and size for surgery. Its impact on complication development is controversial.
- Physical examination in a patient with hypospadias may reveal a ventral deficient prepuce, downward glans tilt, deviation of the median penile raphe, ventral curvature, scrotal encroachment onto the penile shaft, scrotal cleft, and penile scrotal transposition. Each of these must be considered for the surgical reconstruction; each has its own degree of impact.
- Regional blockade is an important adjunct to the surgical procedure. Caudal anesthesia can decrease the amount of anesthetic delivered and does not appear to increase the complication rate.

Assessment and Management of Ventral Penile

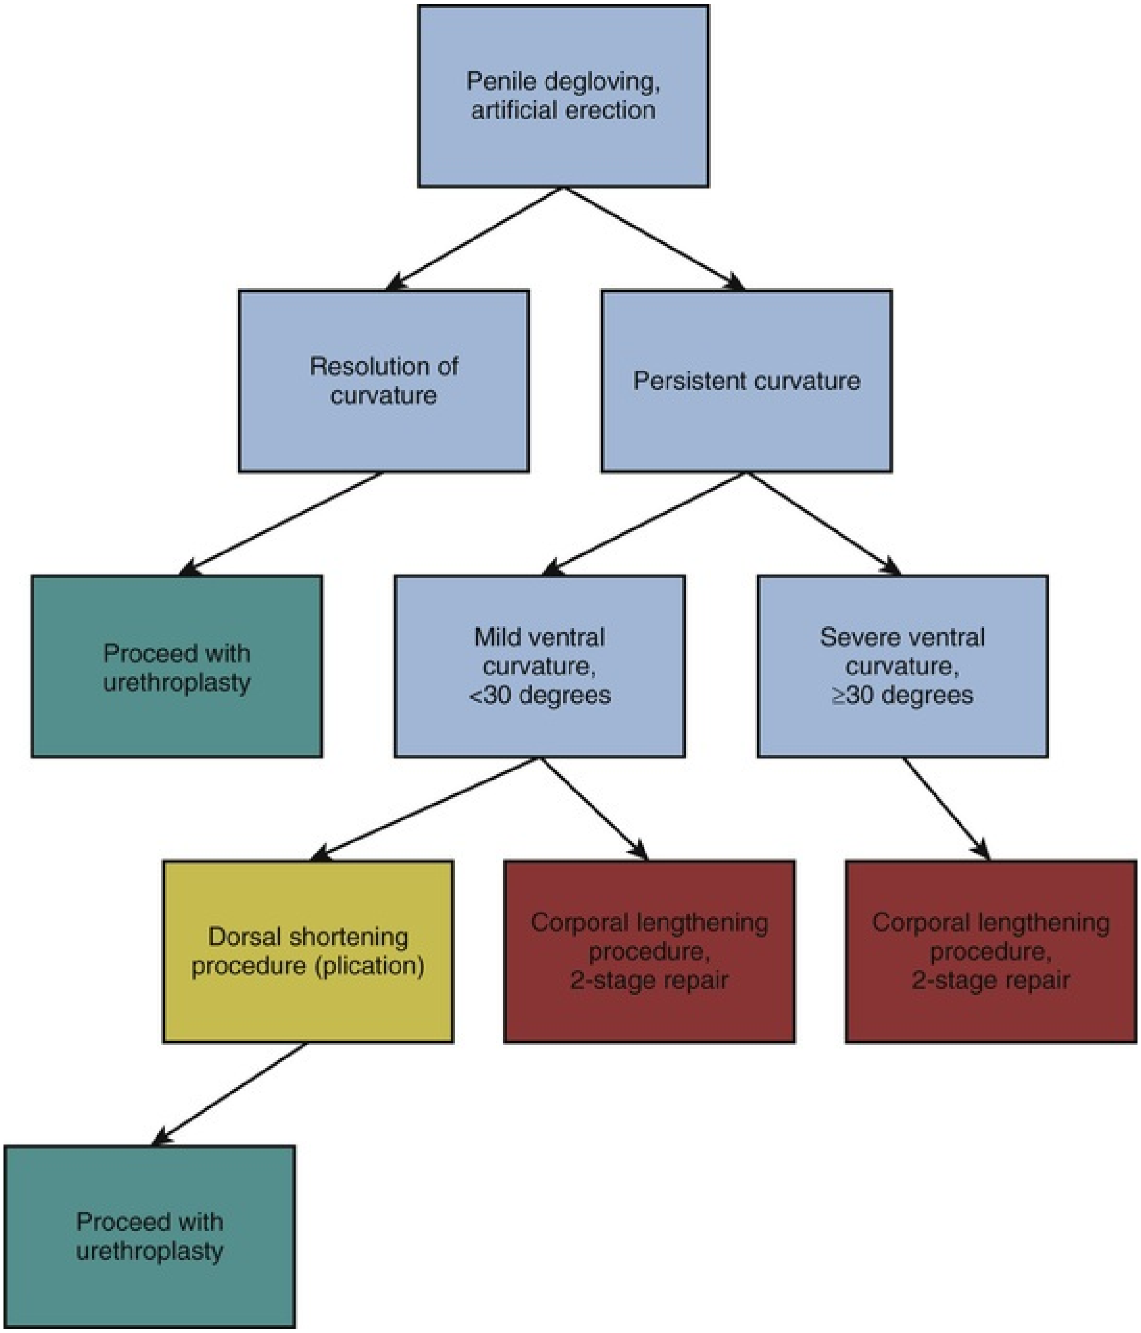
Curvature

Penile curvature, or chordee, occurs in the presence or absence of hypospadias. **The degree of curvature is a major determinant in the selection of a one-stage versus a two-stage repair. The decision to treat curvature centers around the potential functional and cosmetic concerns that males can have as they mature into adulthood. Assessment of males with untreated congenital curvature or those with Peyronie disease suggests that as little as 20 to 30 degrees of ventral curvature may result in significant morbidity for patients, including difficulties with intercourse and the patient's dissatisfaction of the appearance of the penis** (Menon et al., 2016; Walsh et al., 2013).

Curvature may result from shortened ventral skin, a short urethra, or from intrinsic curvature of the erectile bodies. The cause of curvature is extremely difficult to assess outside of the operating room. Parents should be asked if they note a history of curvature with erections or may even document this in their son with photos, but **the definitive assessment is done via artificial erection in the operating room after the penis has been degloved.** In 1973 Devine and Horton developed a staging system based on the degree of dysplasia of Buck fascia, dartos, and corpus spongiosum (Devine and Horton, 1973). Donnahoo et al. (1998) expanded this further, dividing curvature into a classification system of 4 groups: skin tethering; dysgenetic Buck and dartos fascia; corporal disproportion; and congenitally short urethra. Each component can be present to varying degrees, increasing the complexity of the defect and repair. Although this system was used to describe chordee in boys without hypospadias, its concepts are relevant to the curvature noted in hypospadias.

An attempt to assess the degree of curvature should be made in the operating room before skin incision. Passage of a catheter or bougie à boule into the meatus will provide an assessment of the overlying tissue, indicating the quality of the urethra and the ventral skin (see Fig. 45.5). A circumscribing incision is made and the penis is degloved as far as the penoscrotal junction, to excise dysplastic dartos tissue. **Artificial erection should then be performed, typically with a tourniquet placed at the penoscrotal junction and injection of sterile normal saline** (Gittes and McLaughlin, 1974)**. Alternatively, in small boys the surgeon can compress the corpora at the base of the penis to approximate an erection without injection.** Curvature can occur at the base of the penis and can be obscured by the presence of a tourniquet. Pharmacologic erection with prostaglandin can be induced as an alternative to saline injection (Kogan, 2000).

Penile curvature has traditionally been treated by the surgeon in a subjective manner, typically categorized as mild (<30 degrees), moderate (30–45 degrees), or severe (≥45 degrees). We, along with several other institutions, use an orthopedic device called a goniometer that functions as a protractor to objectively measure the degree of curvature (Fig. 45.7). Our experience with this device is that the degree of curvature was being underestimated when the “eyeball” test alone was used. Electronic alternatives, which include apps for use on phones and tablet devices, are starting to emerge as well. Regardless of the approach we feel that the assessment should be standardized.



Penile degloving, artificial erection
Resolution of curvature
Persistent curvature
Proceed with urethroplasty
Mild ventral curvature, <30 degrees
Severe ventral curvature, ≥30 degrees
Dorsal shortening procedure (plication)
Corporal lengthening procedure, 2-stage repair
Corporal lengthening procedure, 2-stage repair
Proceed with urethroplasty

FIG. 45.7 Algorithm for management of penile curvature. Once the penis is degloved, artificial erection is performed. If the curvature is resolved, the urethroplasty can be completed. If there is persistent penile curvature, we use a measurement of 30 degrees as the defining measurement for performing a dorsal plication or a corporal lengthening procedure. If the surgeon is concerned about the quality of the ventral shaft skin in spite of curvature of less than 30 degrees, a corporal lengthening procedure can be considered.

The degree of penile curvature drives the decision for a single versus two-stage repair (Fig. 45.8). Although no consensus exists for treatment of specific degrees of curvature, most seem to agree that a dorsal plication is sufficient for curvature less than 30 degrees (Springer et al., 2011). If curvature is more severe than 30 degrees, the next step would be to divide the urethra. Some severe cases of ventral curvature have a meatus proximal to the point of maximal bend so that urethral division is not necessary. Persistent curvature greater than 30 degrees at this point would warrant a corporal lengthening procedure, which in our hands requires transection of the corpora spongiosum distal to the urethra or transection of the urethra (Steven et al., 2013).

Sterile saline is injected via a butterfly needle with a tourniquet in place at the base of the penile shaft. (B,C) The goniometer with a protractor-like element present to precisely measure the degree of penile curvature. (D–F) The degree of penile curvature displayed without a measuring device. (D–F courtesy Rafael Gonzalbez.)

Dorsal shortening techniques, first described by Nesbit, involve excising an ellipsoid segment of tunica albuginea and closing this defect in a transverse orientation, shortening the dorsum of the penis (Fig. 45.9) (Nesbit, 1965). **Anatomic studies by Baskin identified an area on the dorsal midline that was free of any neurovascular tissue, allowing a modified plication by placement of a single, midline plication suture through the tunica albuginea to correct curvature** (Baskin et al., 1998). Contrary to Baskin's original description, we prefer to incise the tunica albuginea in the midline dorsally until the corporal tissue is visualized. The defect is then closed to approximate the raw edges transversely in a Heineke-Mikulicz fashion. This is performed using either a nonabsorbable or a long-lasting absorbable suture. Advantages of the plication approach are that it is a simpler procedure and does not limit subsequent ventral penile shaft skin coverage options. Disadvantages include possible injury to the neurovascular bundle (if the plication is performed off the midline axis) and the potential for recurrence of curvature. Elevating the neurovascular bundle before placing plication sutures may reduce the risk of neural injury (Dean et al., 2000). Plication may be less effective in boys with more severe curvature, particularly when the tunica albuginea is not incised. Of particular concern is that recurrent curvature at puberty is more common after plication compared with ventral lengthening (Ozkuvanci et al., 2017). In our experience, plication works well for mild curvature (<15 degrees), and many use this technique for up to 30 degrees of curvature (see Fig. 45.7).

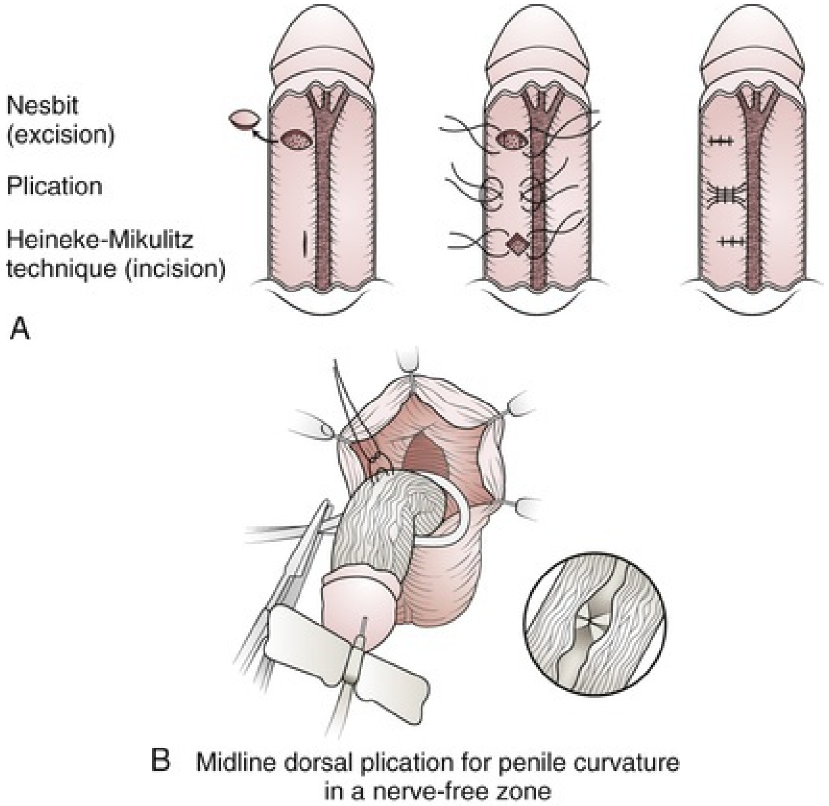

FIG. 45.9 (A) Description of three different plication techniques to correct penile curvature. Nesbit plication technique: an excisional biopsy of dorsal tunica albuginea is made opposite the point of maximal curvature. In a similar fashion, others have described performing a plication without incising the tunica albuginea. The Heineke-Mikulitz technique involves a vertical incision in the tunica albuginea and horizontal closure of the defect to shorten the dorsum of the penis. For each of these techniques the incisions and/or plications are made in parallel on either side of the neurovascular bundle, only one side is displayed for simplicity. (B) The midline (Baskin) plication technique, similar to the Heineke-Mikulitz approach. A single midline plication is performed in the avascular plane of the penis. (A, From Nyirady P: Management of congenital penile curvature. *J Urol* 179:1495–1498, 2008; B, From Baskin LS: Anatomical studies of hypospadias. *J Urol* 160:1108–1115, 1998.)

Several options exist for ventral corporal lengthening procedures (Fig. 45.10). **The basis for each procedure involves single or multiple ventral incisions opposite the point of maximal curvature, releasing the ventral tension on the tunica albuginea to straighten the phallus.** Multiple superficial incisions into, but not through, the tunica albuginea of corpus cavernosa to release the tension on the ventral surface of the penis are called “fairy cuts.” Several (1 to 3) full-thickness incisions into the tunica albuginea without grafting are referred to as transverse corporotomies and have been popularized in the STAG technique, as described in the proximal hypospadias section (see Fig. 45.10A) (Pippi Salle et al., 2016; Snodgrass and Bush, 2017a). A single full-thickness corporotomy extending from 9 o'clock to 3 o'clock or until there is mild reverse hinging of the penis, with subsequent grafting, is our preferred method for ventral lengthening (▶Videos 45.1 and ▶45.2). Subsequent graft options include either autologous tissue (dermal graft [Devine and Horton, 1975], tunica vaginal flap [Braga et al., 2007b] or graft) or nonautologous tissue (AlloDerm, small intestinal submucosa (Braga et al., 2008; Castellan et al., 2011; Fig. 45.10B). The dermal graft procedure is depicted in Fig. 45.10C–F.

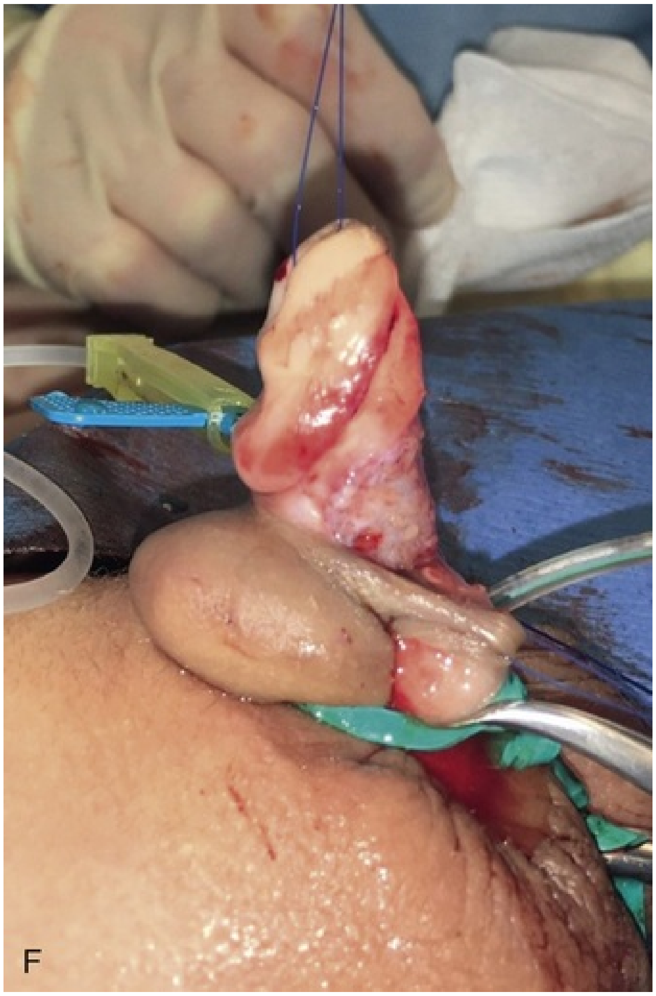

FIG. 45.10 (A) The multiple ventral tunica albuginea corporotomies without grafting as described in the staged tubularized autograft (STAG) repair. *Arrows* are pointing to the transverse corporotomies, which are made full thickness through the albuginea; in this particular example three incisions have been made. (B) Three approaches to ventral penile lengthening. A tunica vaginalis flap, tunica vaginalis graft, and dermal graft are depicted. Each approach is performed after division of the urethral plate and incision of the tunica albuginea. (C–F) show four live surgical images of a dermal graft. First a single, full-thickness transverse incision is made in the tunica albuginea, opposite the point of maximal curvature (C). A dermal graft is then measured 20% larger than the defect in the tunica to allow for graft contracture without shortening the penis (D). This is then sutured in place in a watertight fashion (E). Repeat artificial erection is performed to confirm that penile curvature is fully corrected (F). (A, From Snodgrass W: Staged tubularized autograft repair for primary proximal hypospadias. *J Urol* 198:680–686, 2017. B, From Braga LH: Outcome analysis of severe chordee correction using tunica vaginalis as a flap in boys with proximal hypospadias. *J Urol* 178(suppl4):1693–1697, 2007.)

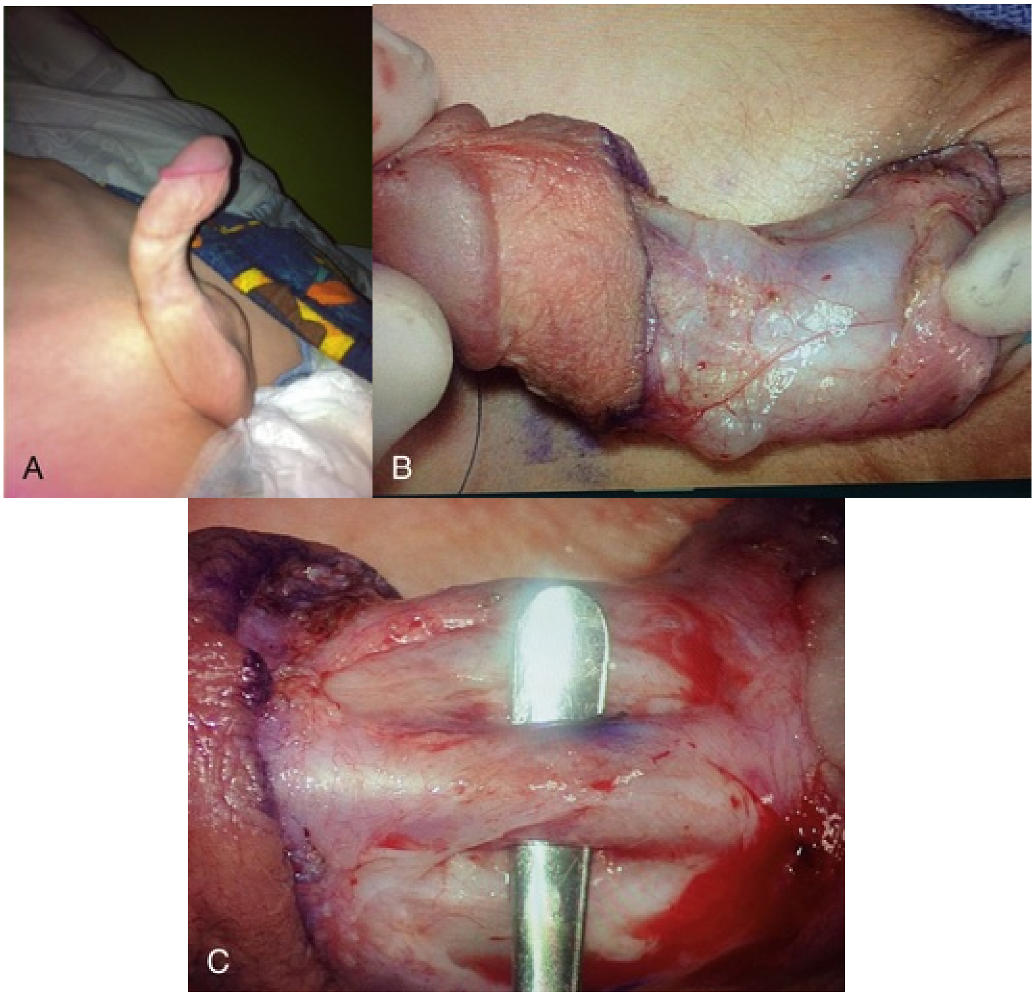
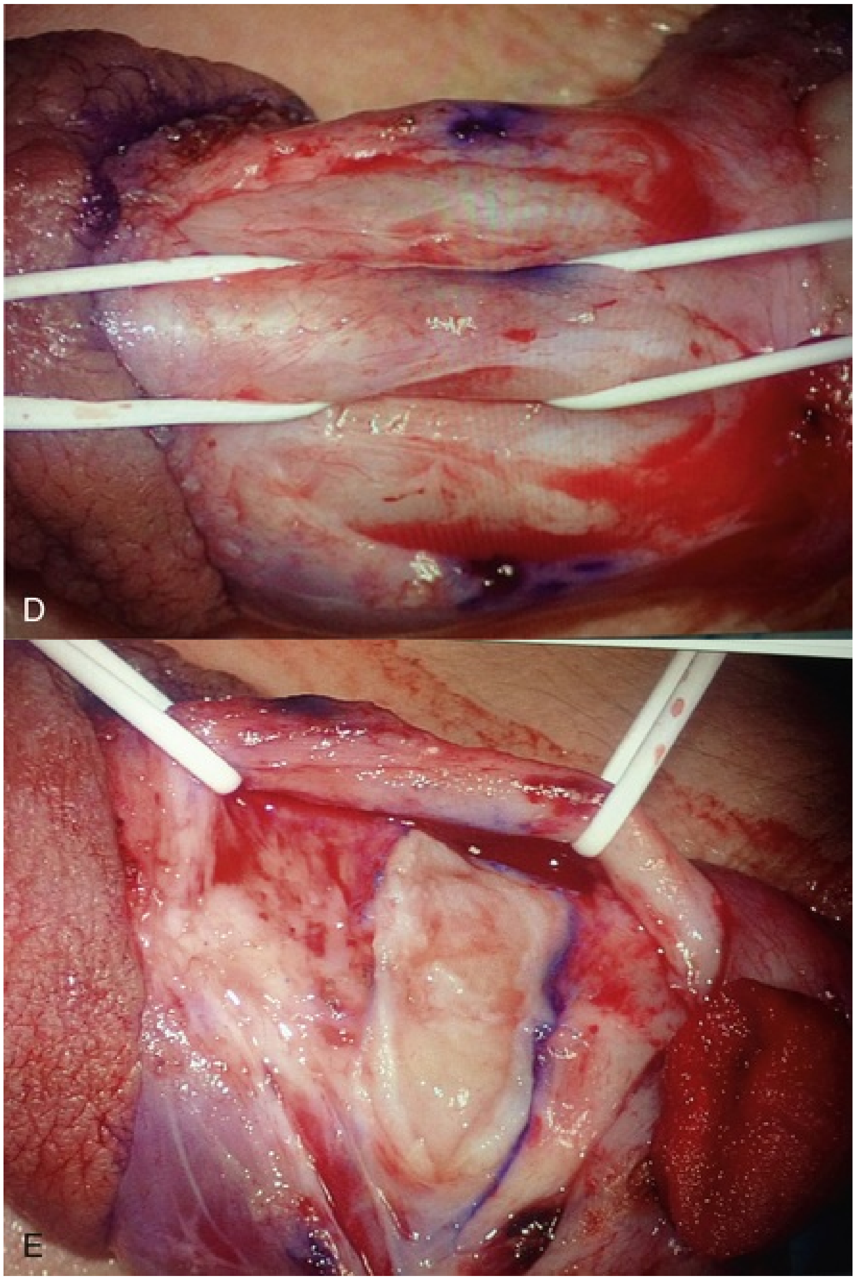
The choice of corporal lengthening approach is left to the discretion of the

surgeon: no series has formally compared the three ventral lengthening procedures. Benefits of the corporal lengthening procedure(s) include an increase in length of the penis and improved results for severe curvature. Concerns include a longer and more complicated procedure compared with plication, a limitation in ventral skin coverage options, and a potential higher risk of erectile dysfunction. In our experience, patients having undergone pediatric penile lengthening procedures have not had issues in adulthood with erectile function.

Curvature may worsen as these boys progress through puberty and undergo more significant penile growth. Therefore it is important to properly identify and correct curvature at the time of the initial repair (Barbagli et al., 2006; Braga et al., 2008). Direct comparison of the approaches to curvature described earlier is difficult for two reasons: first, there is a lack of standardized definitions of the degree of curvature (lack of objective instrumentation) and second, there are few well-designed and executed comparative studies. In a study of 51 patients with perineal hypospadias with severe ventral curvature with a minimum follow-up of 5 years, 5 of 23 (21%) of patients who underwent dorsal plication developed recurrent curvature, compared with 0 of 11 patients who underwent a two-stage repair with corporal grafting (Gershbaum et al., 2002). **In a series of 100 boys operated upon in Toronto, Braga found an increased rate of recurrent penile curvature after dorsal shortening with plication when compared with boys who had ventral lengthening with corporal grafting (28% vs. 9%, $P = .03$)** (Braga et al., 2008). These results corroborate our clinical experience in that corporal lengthening procedures better correct more severe curvature. This is of particular importance as boys with persistent penile curvature after primary repair, in pre- and postpubertal age groups are challenging to correct, sometimes requiring several staged procedures to achieve an acceptable outcome. This makes it imperative that penile curvature is properly diagnosed and corrected. Long-term assessment is going to be essential for these boys to determine the ideal approach to ensure lasting success and proper function.

Some have referred to boys with severe ventral curvature with a normal urethra as having "congenital penile curvature" (Daskalopoulos et al., 1993; Devine and Horton, 1973; Kramer et al., 1982). Biopsies of tunica albuginea tissue in these boys show that the extracellular matrix and collagen fibers are misaligned and disrupted (Darewicz et al., 2001). Reports have delineated a progressive assessment and treatment algorithm that begins with penile degloving and plication, whereas severe cases may require transection of the urethra at the point of maximal bend, followed by one of the various grafting techniques (Bhat et al., 2008; Tang et al., 2007). This approach requires a staged repair to reconnect the urethra after the chordee has been corrected. **We have developed a successful technique that allows the normal urethra to be mobilized in situ, allowing a corporotomy and graft in one operation, thus avoiding a secondary procedure** (Zaontz and Dean, 2016; Fig. 45.11). We believe this will provide a more secure correction of the curvature while obviating a second repair, an experience shared by others (McQuaid et al., 2016). Recurrent curvature can occur in 2% to 15% of these boys, particularly with plication technique, a reality that should be discussed with parents before repair (Donnahoo et al., 1998; McQuaid et al., 2016; Tang et al., 2007).





D
E

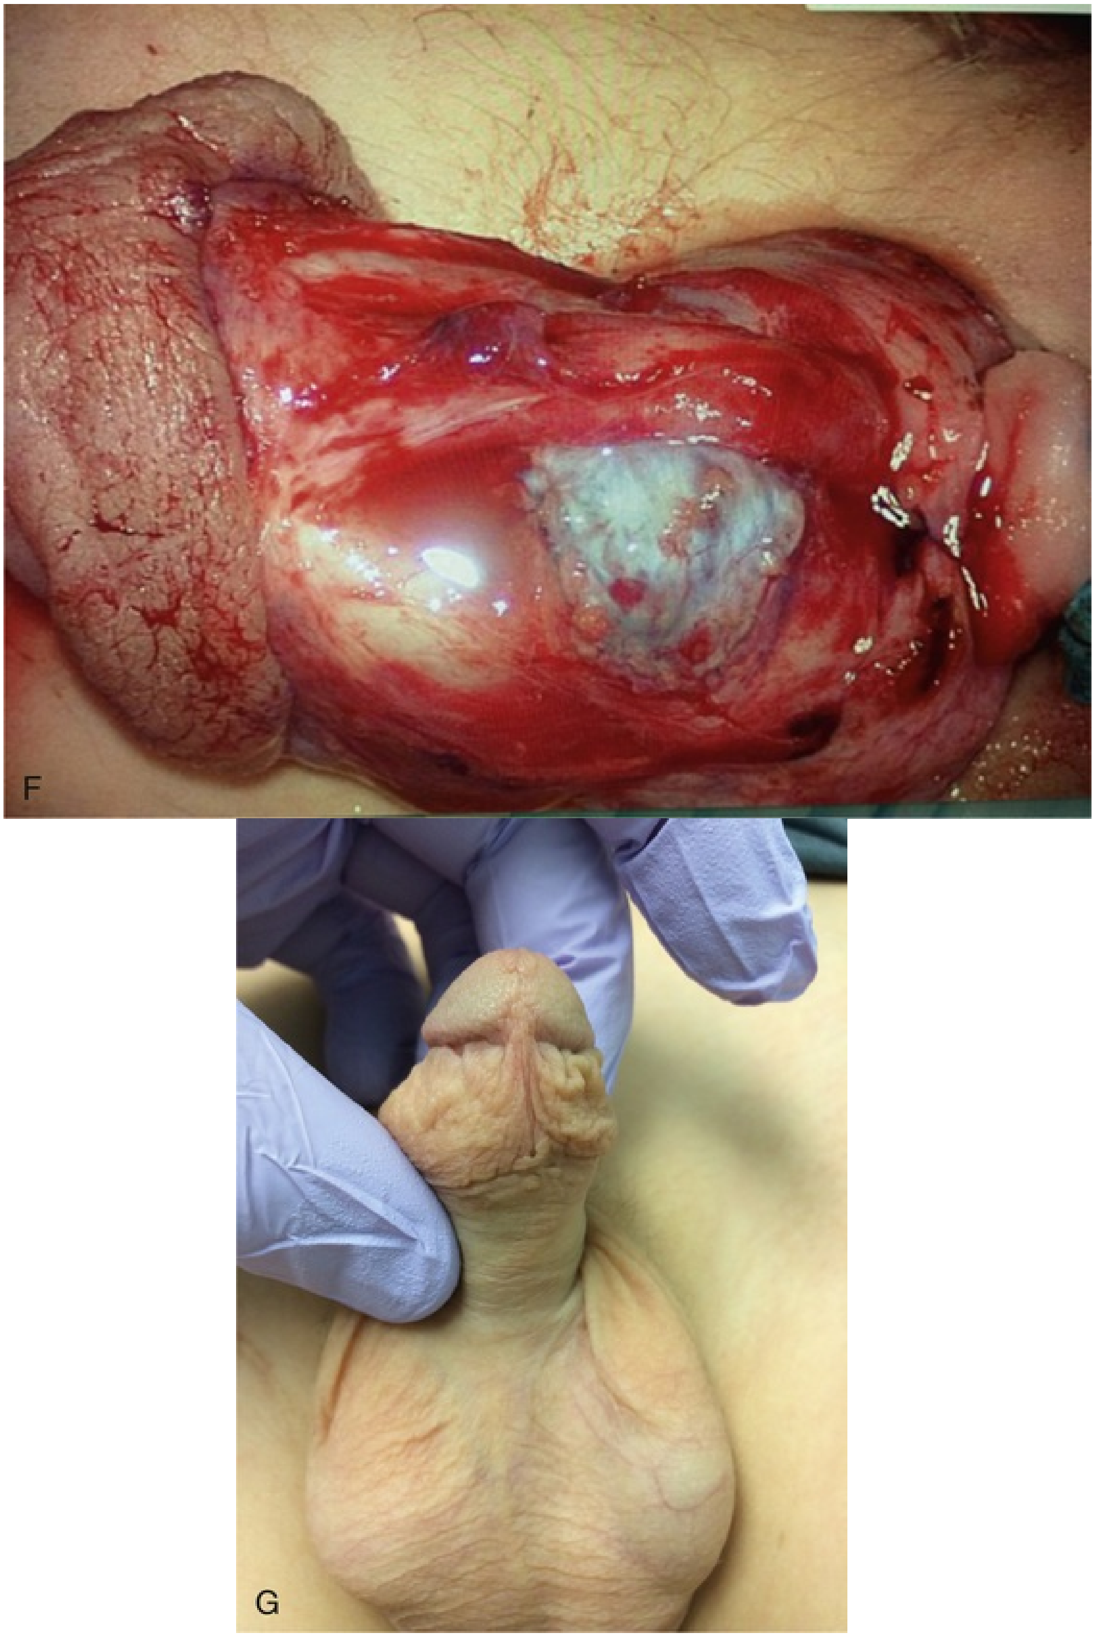


FIG. 45.11 Management of a boy with ventral chordee without hypospadias. (A) Ventral penile curvature is depicted with an erection. Note

that the boy is already circumcised and that the urethral meatus is in a normal position. (B) The penis is degloved, exposing the corpus spongiosum, which is normal. (C,D) The urethra is mobilized off of the corporal bodies, and a transverse incision is made in the tunica. This corrects the penile curvature; therefore the urethra is not divided. (E) A dermal graft is placed into the defect in the tunica albuginea. (F) the urethra is released and the dermal graft is in place. (G) Twelve months after repair, the penis is straight with no evidence of persistent chordee.

Finally, a number of children may have dorsal and/or lateral penile curvature, which can be corrected most of the time with simple plication techniques. However, in rare instances of severe dorsal and or lateral curvature, a patch graft may be necessary as well as the potential need for urethral and/or neurovascular bundle mobilization. Others have noted a higher complication rate with plication in boys with lateral, dorsal, or spiral anomalies that result in a curved penis (McQuaid et al., 2016). These lateral areas of the corpora are theorized to have a thinner albuginea when compared with the dorsum of the penis, limiting the relative effectiveness of plication techniques.

Key Points

- Curvature less than 30 degrees can be straightened by dorsal plication without clinically apparent shortening of the penis.
- Objective measurement of penile curvature, as identified by artificial erection after penile degloving, is a key element of the surgical procedure. Curvature must be assessed and properly corrected.
- Transection of the urethral plate and/or ventral corporal grafting are reserved for cases with curvature greater than 30 degrees after degloving and dartos dissection.
- Improperly corrected penile curvature poses a significant morbidity to the patient, often necessitating several procedures to achieve a straight penis.

General Considerations of Surgical Repair

Aside from the previously mentioned psychological benefits of operating on a young infant, the literature is split on the potential impact that age has on surgical outcomes. Hypospadias repair in boys younger than 6 months of age has been reported as more successful when compared with surgery on

older boys (Perlmutter et al., 2006; Yildiz et al., 2013). **However, two other studies showed no such benefit** (Bush et al., 2013b; Ziada et al., 2011). A systematic review comparing outcomes in North America, Europe, and China, including more than 16,000 patients in 113 manuscripts, identified fewer complications in younger boys at the time of primary repair, and recommended correction by the age of 18 months (Lu et al., 2012). A study by Weber et al. that examined the psychological effects of hypospadias surgery before and after 18 months of age found that later surgery had no negative impact on the long-term emotional impact to the patient (Weber et al., 2009). With this in mind, we recommend beginning the surgical process with the first stage at 6 months. This will likely result in adherence to the AAP-recommended age range of 6 to 18 months for the surgical reconstruction or reconstructions. **Hensle et al.** (2001) **reported that adult hypospadias surgery, for primary and reoperative cases, is associated with a higher than anticipated complication rate, in spite of nearly all patients undergoing a more distal repair. This is in contrast to subsequent studies, which suggest no increased risk of repair in adult patients** (Adayener and Akyol, 2006; Snodgrass et al., 2014b).

Antibiotics are often administered in the perioperative period, preoperatively and as prophylaxis, because of concerns for UTI and/or wound infection (Hsieh et al., 2011). Alternatively, prophylactic antibiotics can be administered at surgery and then at the time of stent removal. Given the shift in concern for overadministration of antibiotics and its role in developing resistant organisms, adverse drug reactions, and changes to the microbiome, several studies have assessed the need for antibiotics in hypospadias repair. The first studies elucidating the role of prophylaxis with an indwelling stent suggested a decrease in the UTI rate, although these boys were asymptomatic and positive cultures represented asymptomatic bacteriuria instead of a true UTI (Shohet et al., 1983; Sugar and Firlit, 1988). A randomized study by Meir and Livne (2004) of patients undergoing the tubularized, incised plate (TIP) procedure found that those who received continuous antibiotic prophylaxis (CAP) were less likely to develop a complicated UTI (3 vs. 12, $P < .05$) and complications (5/52 [9.6%] vs. 13/49 [26.5%], $P < .05$). Others have found CAP to have no impact on complication development, either surgically or infection related, whereas others have even questioned the need for preoperative antibiotics (Baillargeon et al., 2014; Kanaroglou et al., 2013; Smith et al., 2017; Zeiai et al., 2016). Because postoperative UTI or wound infection is so rare after hypospadias repair, this controversy will not likely be sorted out without a large multicenter trial. Our approach varies by surgeon, ranging from daily prophylaxis for the duration of the indwelling urethral stent to a 3-day course starting the day before stent removal.

Sutures used in hypospadias repair must provide sufficient strength while the urethroplasty heals yet should dissolve before suture tracks can epithelialize and lead to fistulous tracts or suture sinuses. Moreover, the suture material should elicit minimal inflammatory response. Hypospadias-specific studies comparing absorbable sutures are few and unfortunately inconclusive. Bartone et al. (1987) found chromic to be superior to polydioxanone (PDS) because of concerns for wound infection, inflammatory reaction, and poor wound healing. In a similar study, DiSandro and Palmer (1996) found the use of rapidly absorbing sutures such as chromic and polyglycolic acid (Vicryl) had a significantly lower complication rate in urethroplasty when compared with the more slowly absorbing PDS. More recent series have also suggested a lower complication rate with Vicryl suture as opposed to monofilament sutures (Snodgrass and Yucel, 2007; Uygur et al., 1998). Regardless of the suture used, modern techniques require use of absorbable, microsurgical-size suture for fine tissue approximation.

Given the complexity of hypospadias repair, even for distal hypospadias, it is not surprising that a learning curve exists. **Higher surgeon volume has been directly correlated to lower complication rates** (Horowitz and Salzhauer, 2006; Lee et al., 2013; Titley and Bracka, 1998)**. Studies comparing experienced surgeons to less experienced surgeons have shown a decreased complication rate for more experienced surgeons** (Snyder et al., 2005a)**. In a similar fashion, comparison of individual surgeon results indicates that time from completion of fellowship training and increase in case volume significantly reduce the incidence of surgical complications** (Horowitz and Salzhauer, 2006). A large population study of 108 surgeons performing distal hypospadias repair found that higher yearly case volume led to a significant decrease in postop complications (Lee et al., 2013).

The use of hair-bearing skin for urethroplasty is discouraged because postpubertal hair growth renders the neourethra susceptible to stone formation and recurrent UTIs. Surgical technique is as important a factor for outcomes as surgical approach. Gentle tissue handling prevents crush injury and preserves blood supply to tissues, which is critical to predictable wound healing. It is imperative that the wounds are closed without tension. Wounds closed under pressure reduce capillary flow and promote ischemia.

Ischemia results in fibrosis and contraction of tissues, predisposes the wound to infection, and potentiates the breakdown of suture lines. Tissue trauma can be minimized by the use of fine forceps, skin hooks, and stay sutures. Intraoperative magnification facilitates this process and helps to identify delicate blood supply and proper tissue approximation. Flaps must be mobilized generously to minimize tension on suture lines and to prevent ischemia. Subcuticular neourethral approximation with epithelial inversion has been shown to decrease complications when compared with full-thickness suturing, as has dual-layer neourethral closure (Cimador et al., 2004; Ulman et al., 1997).

Although use of healthy and well-vascularized tissue is vital, the use of second-layer vascularized tissue coverage over the neourethral repair further reinforces blood supply. The use of multiple overlapping tissue layers is important in the reduction of complications so long as the additional layers do not compromise capillary flow. Dartos interposition flaps increasing the vascularized layers superficial to the urethral closure help reduce fistula formation after TIP repair (Savanelli et al., 2007). This can be done in multiple ways, including the preputial de-epithelialized dartos flap, adjacent de-epithelialized skin flaps in the absence of preputial tissue, tunica vaginalis, and/or the use of the corpus spongiosum for coverage (Fig. 45.12 and ▶Video 45.3; Basavaraju and Balaji, 2017; Chatterjee et al., 2004; Churchill et al., 1996; Smith, 1973; Snow et al., 1995). Belman (1988) initially described a technique of harvesting a dartos flap after transposing Byars flaps around to the ventrum (▶Video 45.4). The point where the excess prepuce reaches the proximal edge of the mucosal collar is measured, and a transverse incision is made (see Fig. 45.12). The harvested vascularized tissue is draped over the entire neourethral repair and secured laterally in a running fashion to offset suture lines.

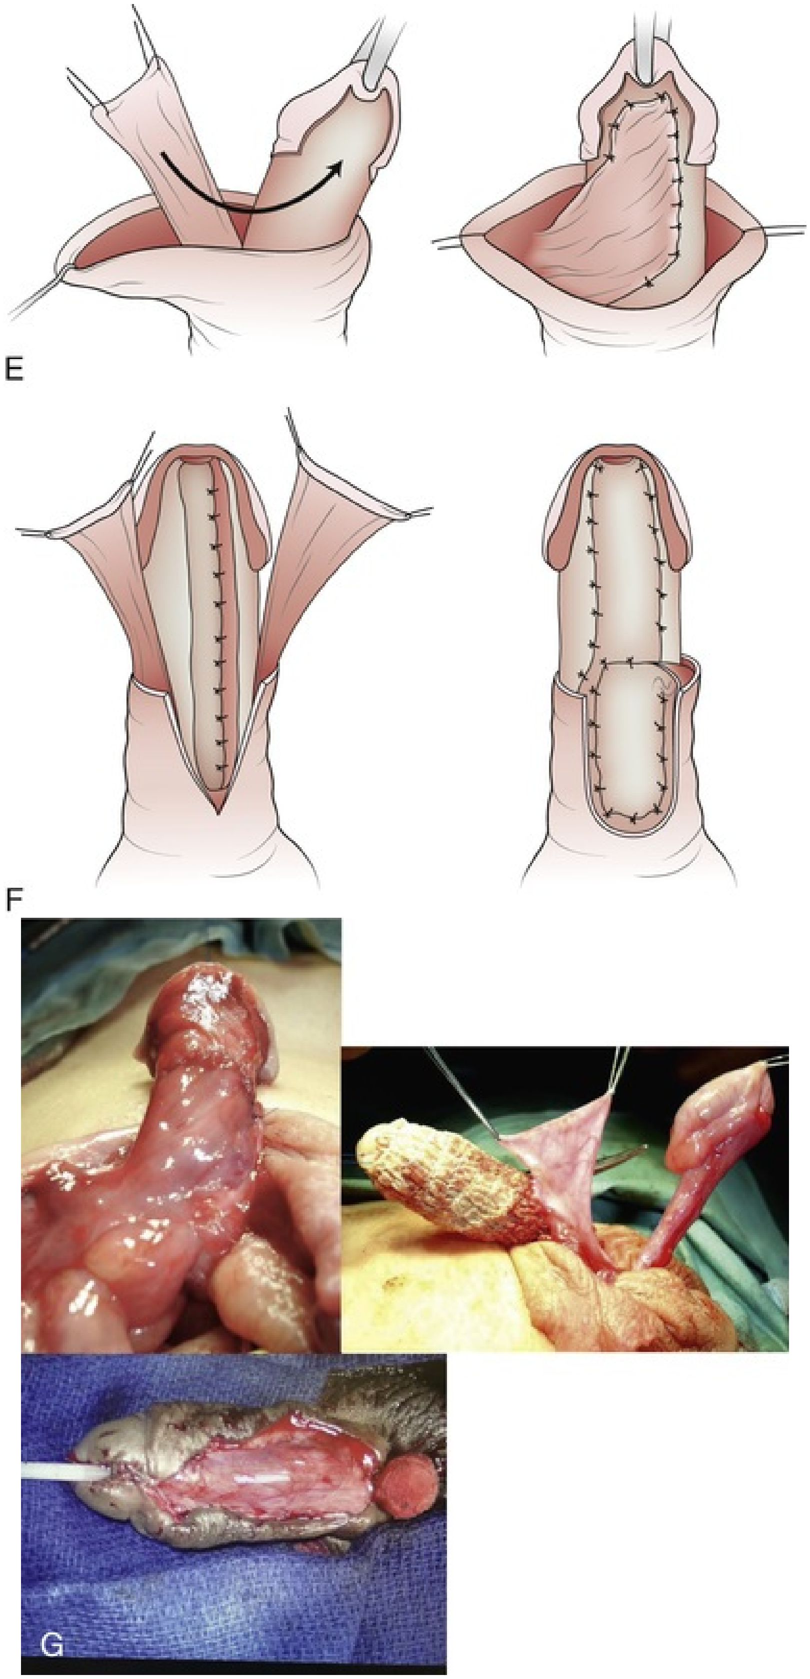

FIG. 45.12 (A) Cartoon depiction of the de-epithelialized Belman flap.

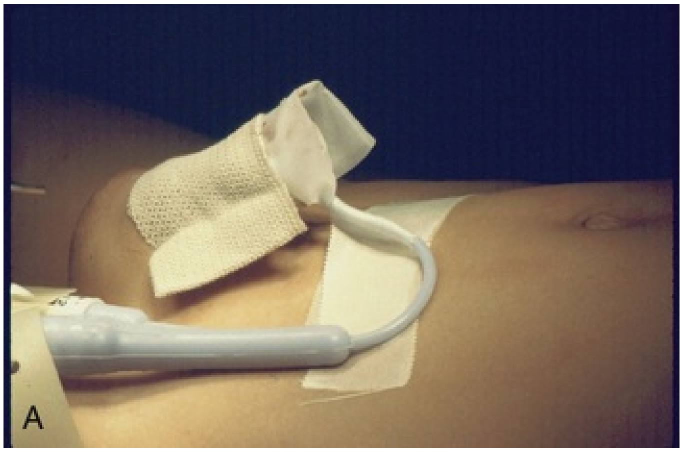
Redundant foreskin is incised dorsally in the midline to the point of yielding a proper skin fit with a circumcision. Byars flaps are rotated ventrally to the midline along either lateral side of the penis. (B–D) represent live surgical pictures depicting the technique. (B) The lateral borders of the redundant skin are marked. (C) The epithelium of the skin is incised and then removed, taking care to preserve the well-vascularized dartos layer. (D) The dartos is then secured as an additional layer of coverage over the urethroplasty, with an offset suture line flanking either side of the urethral closure. (E) Use of bilateral flaps to cover a longer urethroplasty. (F) Depiction of securing the flap in place. (G) Tunica vaginalis flap is harvested as a barrier layer over urethroplasty. Mobilization from the spermatic cord to the external ring prevents subsequent tethering of the testicle and/or penis. (From Belman AB: De-epithelialized skin flap coverage in hypospadias repair. *J Urol* 140[5 Pt 2]:1273–1276, 1988.)

Finally, careful hemostasis should be maintained with the judicious use of pinpoint cautery and a compressive bio-occlusive dressing. Hematoma formation can impede flap healing, resulting in tissue ischemia, and can compromise the repair. The dressing can be formed from an adhesive membrane such as Tegaderm, which is applied circumferentially from the level of the glans to the penoscrotal junction. The glans must be included in the dressing to avoid excessive swelling. Care must be taken to provide even coverage to prevent a constricting ring at the proximal extent of the dressing. Alternatively, a “sandwich” dressing, which provides gentle compression for the first 72 hours postsurgery, can be equally effective (Fig. 45.13). Once the dressing is removed, parents should be counseled that a significant amount of edema and ecchymosis may be present. After dressing removal, application of topical petroleum jelly may help prevent eschar formation and trauma to the tissue as it meets the diaper to further facilitate the healing process.



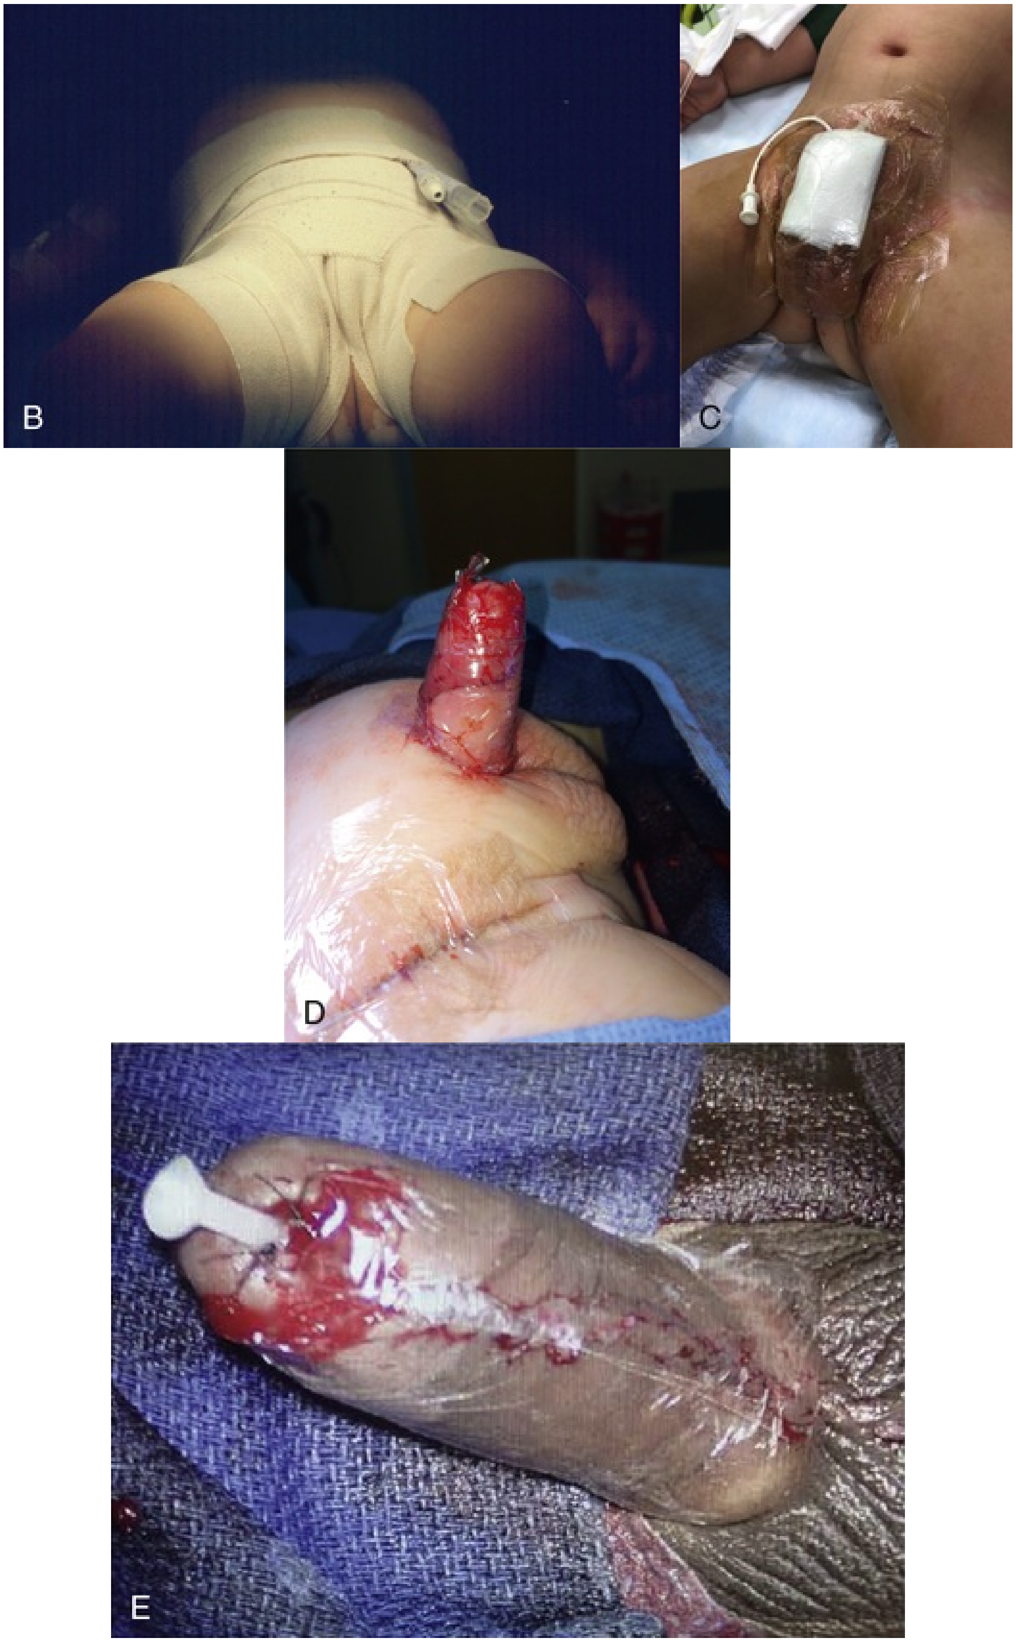


FIG. 45.13 (A,B) Photos of an older type of dressing that includes a Foley catheter in the urethra and subsequently applied extensive amount of

Coban to secure the penis in place. (C) A sandwich dressing, which includes a 6-Fr Kendal stent for the urethra covered by two layers of Tegaderm. (D,E) Simple Tegaderm dressing without a stent and another patient with a drip stent as well.

Key Points

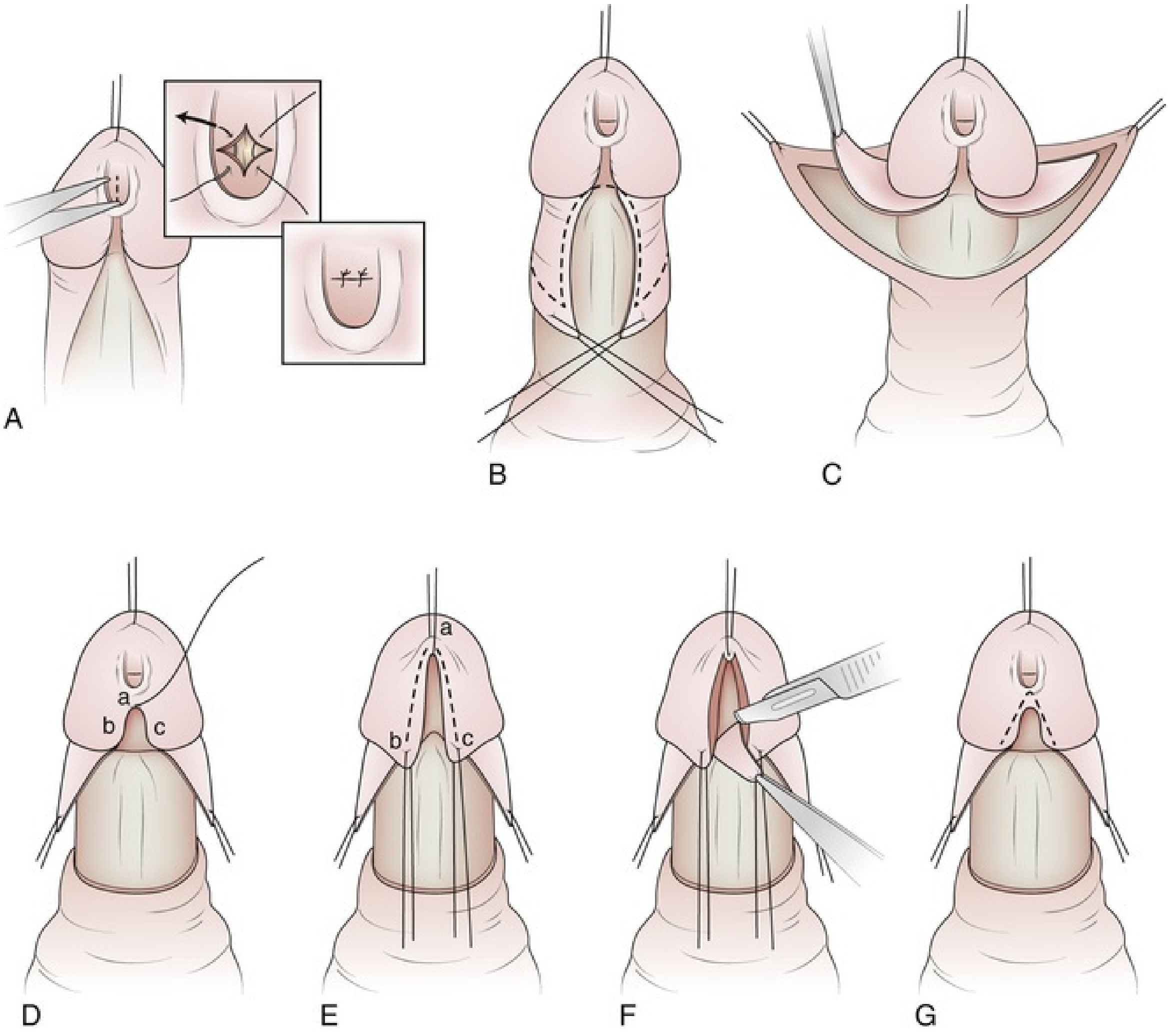
- Higher surgical volume seems to correlate with a lower complication rate in hypospadias repair.
- Nonoverlapping tissue layers, tension-free tissue closure, and barrier layers with well-vascularized tissue increase the success of a repair.

Distal Hypospadias Repair

The literature on hypospadias repairs can be overwhelming, because more than 200 techniques have been described, although the majority are a variation of an established approach. The basic tenets of repair include identification and correction of penile curvature, urethral advancement either with or without urethroplasty, and glansplasty. The skin is then closed, with or without preputioplasty. To simplify the technical variation, urethroplasty techniques can be broadly categorized as those using flaps of local genital skin, those using flaps or grafts of preputial or extragenital tissue, and urethral tubularization. Among the repairs outlined later, a survey of pediatric urologists identified the TIP technique was used more than 90% of the time for distal hypospadias repairs and 80% of the time for midshaft repairs (Cook et al., 2005).

Advancement Procedures

Advancement procedures do not require tubularization of the urethral plate and are typically reserved for only the most distal, glanular meatus with minimal to no penile curvature. Urethromeatoplasty uses the Heineke-Mikulicz principle, in which one makes a longitudinal, vertical incision in the ectopic meatus, the edges of which are then closed in a horizontal fashion (Fig. 45.14A). This flattens the posterior urethral plate and achieves a cosmetically normal meatus. This technique is particularly useful in the setting of a stenotic, distal meatus with an associated blind ending pit in the center of a closed glans.



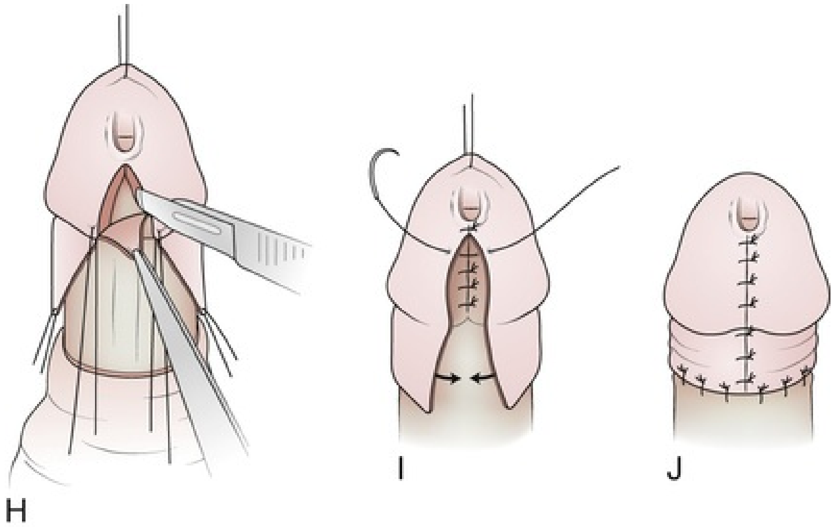


FIG. 45.14 The meatal advancement glanuloplasty (MAGPI) procedure. (A) Heineke-Mikulicz rearrangement with longitudinal incision is made and then closed in a horizontal fashion. (B) Mucosal collar is marked with holding sutures placed. (C) Penis partially degloved. (D) Holding suture placement *(a, b, c).* (E) Distal retraction to provide meatal advancement *(a),* vs. proximal retraction *(b, c).* (F) Glanular spongiosum exposed after excision of glans edges. (G,H) Alternatively marker used to inscribe V along glanular edges and V-shaped tissue segment excised. (I) Approximation of the glans in two layers. (J) Completed repair with mucosal collar. (From Zaontz MR, Dean GE: Glanular hypospadias repair. *Urol Clin N Am* 29:292, 2002.)

Duckett (1981) pioneered what was to become one of the most widely used procedures to correct glanular hypospadias, the meatal advancement glanuloplasty (MAGPI) (Video 45.5). The main objective of this procedure is to advance the meatus distally without formally tubularizing the urethra (Zaontz and Dean, 2002; see Fig. 45.14A). We have since modified the original description (Fig. 45.14B). Although once used for many degrees of distal hypospadias, the best candidates have a meatus located on the glans. **Application of this technique at more proximal locations subjects the repair to undue tension, thus increasing the risk of developing a retrusive meatus and/or an abnormal, flattened distal glans. The evolution of this technique from widespread use to a more selective application reveals the critical role that anatomic assessment and proper approach selection plays in optimizing outcomes.**

In 1991 Decter developed the M inverted V glansplasty (MIV), a repair for proximal glanular or a coronal meatus without urethral tubularization, designed to prevent the meatal retraction and abnormal glans shape sometimes seen in the

MAGPI procedure (Decter, 1991; Fig. 45.15; ●Video 45.6). This technique is used when the parameatal skin is sufficiently compliant to allow tension-free distal mobilization of the meatus and the glans should be of sufficient size for glanuloplasty. In addition, the glans configuration (with ventral medial upward angulation) should be conducive for successful implementation of the MIV (Fig. 45.15B). The glans wings dissection is usually, although not always, less deep than with tubularization techniques. This procedure advances the ventral urethral lip distally with well-apposed glanular tissue proximal to the meatus, whereas a cosmetically pleasing mucosal collar completes the repair.

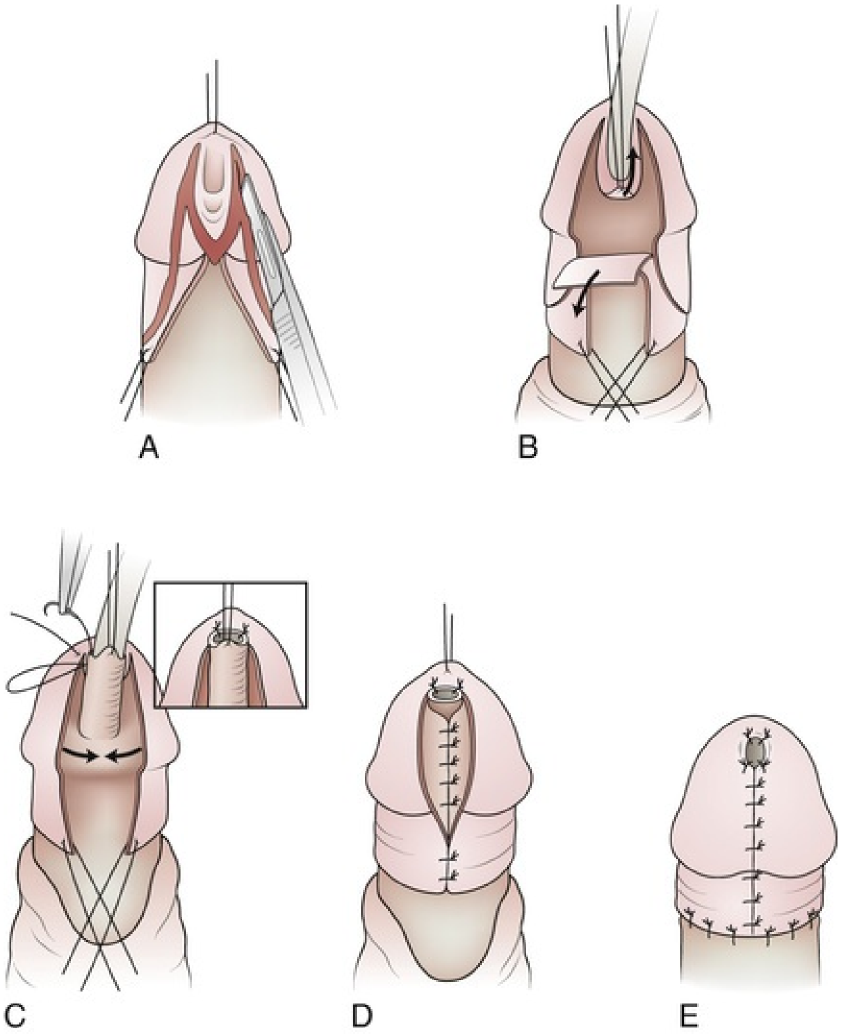

FIG. 45.15 M inverted V glansplasty (MIV) procedure. (A) M-shaped markings made, including mucosal collar followed by incision. (B) Holding suture used to retract meatal tip distally followed by proximal dissection of the ventral tissue. The skin is typically hypoplastic on the distal penile shaft; thus care must be taken to not violate the urethra during this dissection. If

thin but not violated, additional barrier layers can be added to reinforce the repair. (C) Urethromeatoplasty performed followed by ventral approximation of the glans. (D) Two-layer glans closure over the urethral advancement. (E) Completed repair including mucosal collar. (From Zaontz MR, Dean GE: Glanular hypospadias repair. *Urol Clin N Am* 29:292, 2002.)

The urethral advancement procedure, or sleeve technique, incorporates mobilization of the distal urethra by incising the hypospadias meatus at the glans (Koff, 1981). In some instances aggressive mobilization is required. When done in an appropriately selected patient, the mobilization provides increased length to advance the urethra in a tension-free manner into the distal most glans, over which glansplasty is performed (Fig. 45.16). **Concerns for this approach include the potential for devascularization of the mobilized urethra with subsequent urethral stricture and possible retraction of the urethral meatus because of tension caused by the advancement.**

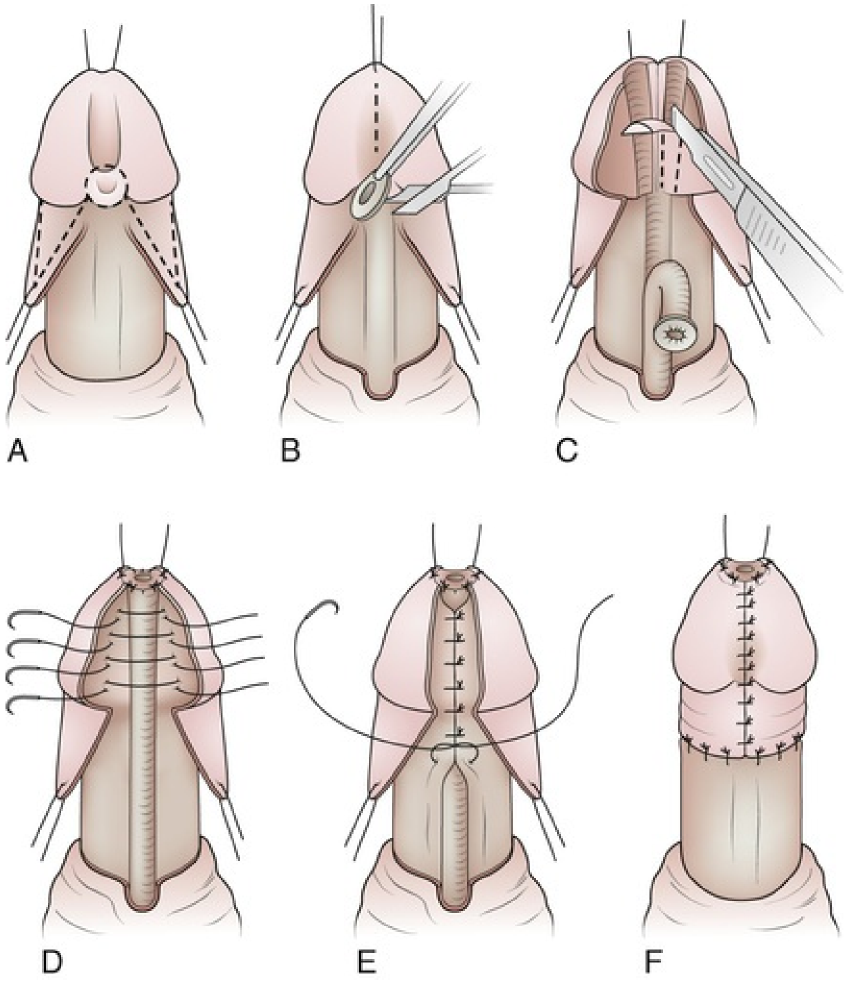

FIG. 45.16 Urethral advancement procedure. (A) Circumferential inscription of meatus and mucosal collar. (B) Degloving of penis followed by mobilization of meatus and urethra. Care is taken to preserve well-perfused urethral tissue, with excision of nonviable segment. (C) Excision of portion of midline spongiosum to allow for proper seating of the urethra in the glans. (D) Proximal deep urethral tissue coverage with glansplasty and approximation of spongiosum. (E) Approximation of superficial glans tissue. (F) Completed repair including mucosal collar. (From Zaontz MR, Dean GE: Glanular hypospadias repair. *Urol Clin N Am* 29:292, 2002.)

Tubularization Techniques

Tubularization techniques incorporate a formal urethroplasty to advance the meatus into a glanular location. These techniques are used in the setting of a more proximal meatus not amenable to advancement, particularly in the setting of curvature that is mild or resolves after penile degloving. These procedures require an astute assessment of the anatomy and application in the appropriate setting, specifically based on the quality of the glans, urethral plate, and periurethral tissue. These anatomic factors can have a big impact on the success of the repair.

The glans approximation procedure (GAP) is a surgical technique designed specifically for patients with proximal glanular/coronal hypospadias who have a wide, deep glanular groove and a noncompliant or “fish-mouth” meatus, which is often present in the MIP variant (Zaontz, 1989; see Fig. 45.3). The pyramid procedure is essentially the GAP with an intact prepuce (Duckett and Keating, 1989). **The glans groove is typically deep and wide enough that if one were to pinch the glans wings together, a normal cosmetic appearance would result. This technique is a modification of the Thiersch-Duplay repair originally described without the extensive mobilization of the glans wings** (Fig. 45.17). **This has since been modified to deeper glans incision and glans wing mobilization, and in our hands, incorporates a two-layer running neourethral mobilization and dartos flap barrier layer**. **As with all reconstructive procedures for hypospadias, attention must be given to the posterior urethral plate to determine the presence of a transverse cleft separating the hypospadias meatus from the distal glans groove.** It is critical that the posterior urethral plate be flat to avoid urine flow deflection as it exits the urethra.

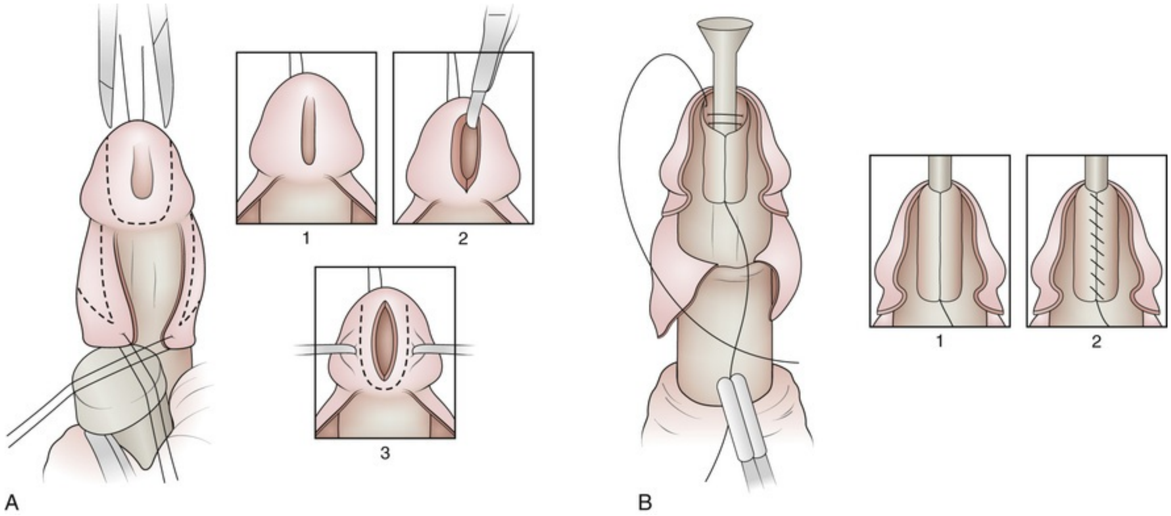

FIG. 45.17 Modified Thiersch-Duplay repair. (A) U-shaped marking line extending down inner prepuce, which is preserved for use in closure of mucosal collar. *Inset* shows narrow urethral plate, which is conducive to TIP modification *(1)* incising urethral plate to determine width *(2)* and lateral marking lines to achieve adequate neourethral lumen *(3).* (B) Tubularization of neourethra. Inset shows first running layer *(1)* and Lembert second running layer *(2).*

Most operations performed in the modern era are modifications of previously developed procedures. The Thiersch Duplay (TD) repair, developed nearly 140 years ago by Thiersch and later Duplay, uses the brilliant concept of urethra tubularization of local tissue distal to the ectopic meatus (Duplay, 1874; Thiersch, 1869). They performed their repair by creating a U-shaped incision made of vascularized skin from the penile shaft, advancing the meatus to the coronal margin. This was later modified for distal hypospadias by covering the repair with a second layer of preputial skin (Allen and Spence, 1968; Belman, 1988). This technique was originally described by Smith and involves de-epithelialization of redundant preputial skin and securing across the repair to provide supplemental blood supply (Smith, 1973). The natural progression was to extend these U-incisions into the distal glans, tubularizing the glans itself over the repair, creating a more cosmetically appealing meatus at the tip of the penis (Firlit, 1987; King, 1970; ▶Videos 45.7 and ▶45.8).

The TD procedure requires a glans of adequate width to allow for an appropriately sized neourethral channel, at least one covering "waterproofing" layer, and glans wings that can loosely approximate over the repair. This technique, which we use frequently in boys with distal hypospadias, is particularly successful if the surgeon adheres to certain parameters (see Fig. 45.17). **Parallel incisions are made lateral to the glans**

groove to equal 12 Fr in diameter; the glans wings must be deeply and widely mobilized to allow for tension-free coverage. Neourethral reconstruction is performed under optical magnification using a double running subcuticular suture. A de-epithelialized pedicle flap is procured from the preputial tissue or the more proximal shaft, should the infant be circumcised, and placed over the entire neourethral repair (Belman and Kass, 1982; Smith, 1973). Should the repair be more proximal, a double dartos flap can be procured from the dorsal prepuce with one flap running distal and one proximal (see Fig. 45.17). **The glans wings are approximated in two layers (spongiosum and then epithelium), followed by the mucosal collar to complete the circumcision defect.**

The TIP procedure, a modification of the TD, is a popular hypospadias surgical technique used worldwide (Cook et al., 2005; Snodgrass, 1994). Rich et al. (1989) noted that the fish-mouth meatal appearance of Mathieu hypospadias repairs or island flap/onlay repairs could be avoided if the posterior urethral plate were incised or hinged, thereby creating a more natural slitlike meatus. The TIP procedure modified the classic TD procedure by incorporating the posterior urethral plate incision as described by Rich. **The midline incision of the posterior urethral plate is designed to improve urethral width to thus allow tubularization of the neourethra in TD fashion, particularly when anatomy would otherwise preclude a tension-free anastomosis with only local tissue. Compared with the superficial incision of a dorsal urethral cleft, the TIP incision is deep and carried to the level just superficial to the corporal bodies, particularly in the setting of a narrow plate or flattened glans. Surgeons must resist the urge to close the urethroplasty too far distally, because this can increase the risk of meatal stenosis. Snodgrass stops his urethral closure 2 to 3 mm proximal to the intended meatal location** (Fig. 45.18). In the original operative description of the TIP procedure, parallel incisions are first made at the lateral edges of the urethral plate followed by a midline longitudinal incision to develop enough width to allow for successful urethroplasty. We have found that no two urethral plates are the same, and obtaining a consistent width throughout the urethroplasty cannot always be achieved in our hands with the TIP. In some cases a narrow plate increases the risk for meatal or urethral stenosis. An experimental animal study demonstrated variable widths upon incising the posterior urethral plate with the additional finding of contraction of the initial incision ultimately leading to a narrower overall width (Eassa et al., 2011). Hence we approach the TIP by first incising the posterior urethral plate, measuring the width obtained, and then making parallel glanular incisions to obtain 12 mm in total width for adequate lumenal diameter. The remainder of the repair proceeds as described for Thiersch Duplay. In our experience, we limit posterior urethral plate incision to situations in which a transverse cleft is present between the meatus and glanular groove to smooth out and flatten the posterior urethral plate to avoid turbulent flow during voiding. **If we consider using the concept of the TIP repair for distal hypospadias, we frequently add an inner preputial graft that we believe protects against future narrowing of the reconstructed distal urethra** (Kolon and Gonzales, 2000).

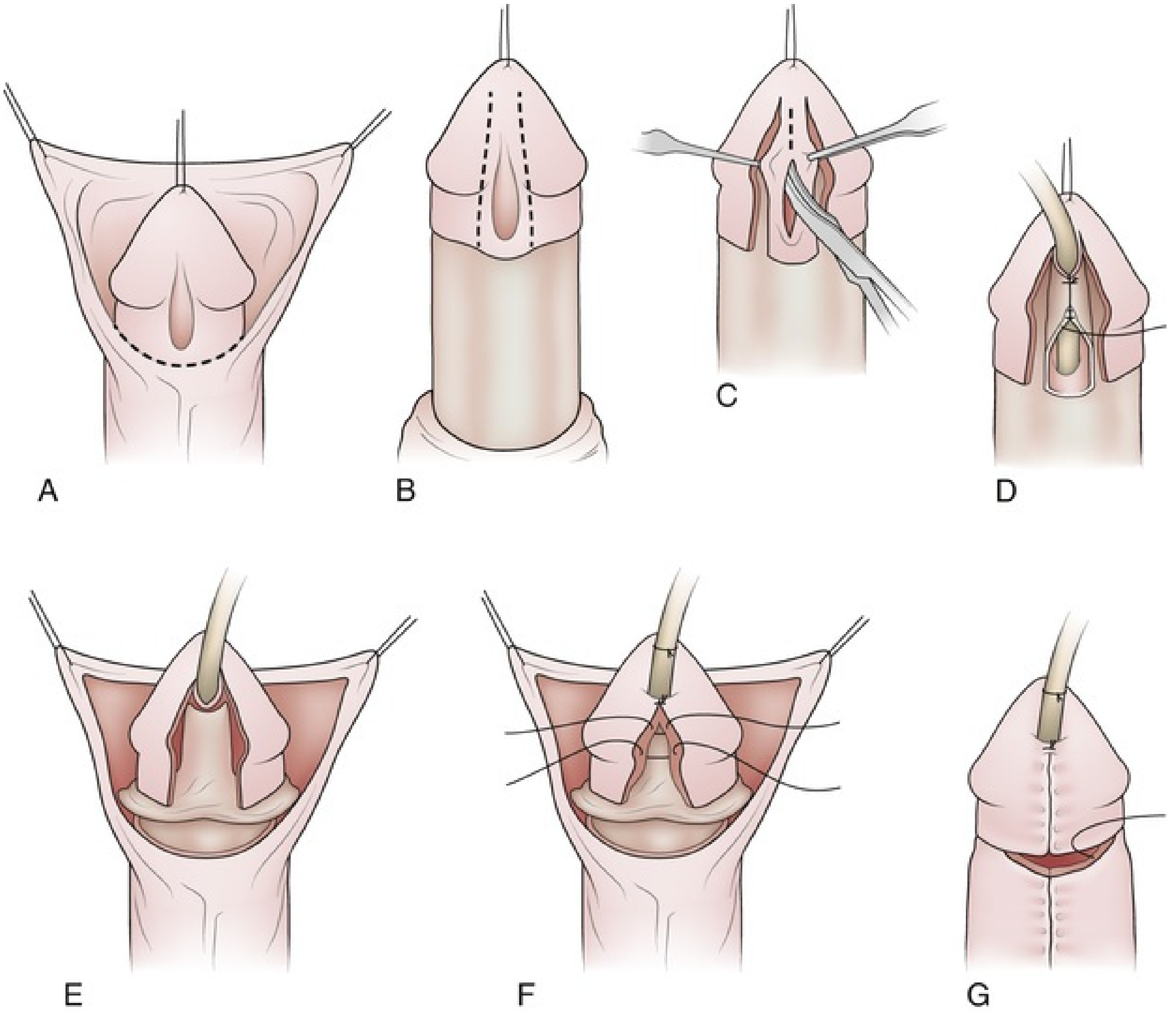

FIG. 45.18 Distal tubularized incised plate (TIP) repair. (A) Circumscribing skin incision. (B) Incision along the visible junction of the glans wings to the urethral plate. (C) Deep, midline incision of the urethral plate extending to the underlying corpora. (D) Tubularizing the urethral plate from distally to

proximally. Note that the first stitch is about 3 mm proximal to the end of the urethral plate, creating an oval opening. (E) The neourethra is covered with a dartos flap. (F) Glansplasty creating the neomeatus and continuing down to the corona. (G) Repair and circumcision completed. (Modified from Snodgrass WT: Snodgrass technique for hypospadias repair. *BJU Int* 95:683–693, 2005.)

The flip-flap technique (Mathieu) is a procedure in which a parameatal-based flap proximal to the meatus is developed, advanced (flipped) onto the deficient urethral plate to augment it, and then closed distally (Devine and Horton, 1973; Mustarde, 1965). Initial incisions are made parallel to the urethral plate and extended proximally for an equal distance such that the raised flap can extend into the distal glans (Fig. 45.19). Theoretical concerns exist regarding the vasculature of the employed flap; if the base of the flap is not sufficiently wide, the blood supply may be compromised, increasing the risk of fistula and stenosis. Others have had concerns for an abnormal, fish-mouth appearance to the meatus. **This technique has been further modified to the so-called slitlike adjusted Mathieu (SLAM) procedure with good outcomes, including an improved appearance to the meatus** (Hadidi, 2012; Fig. 45.20).

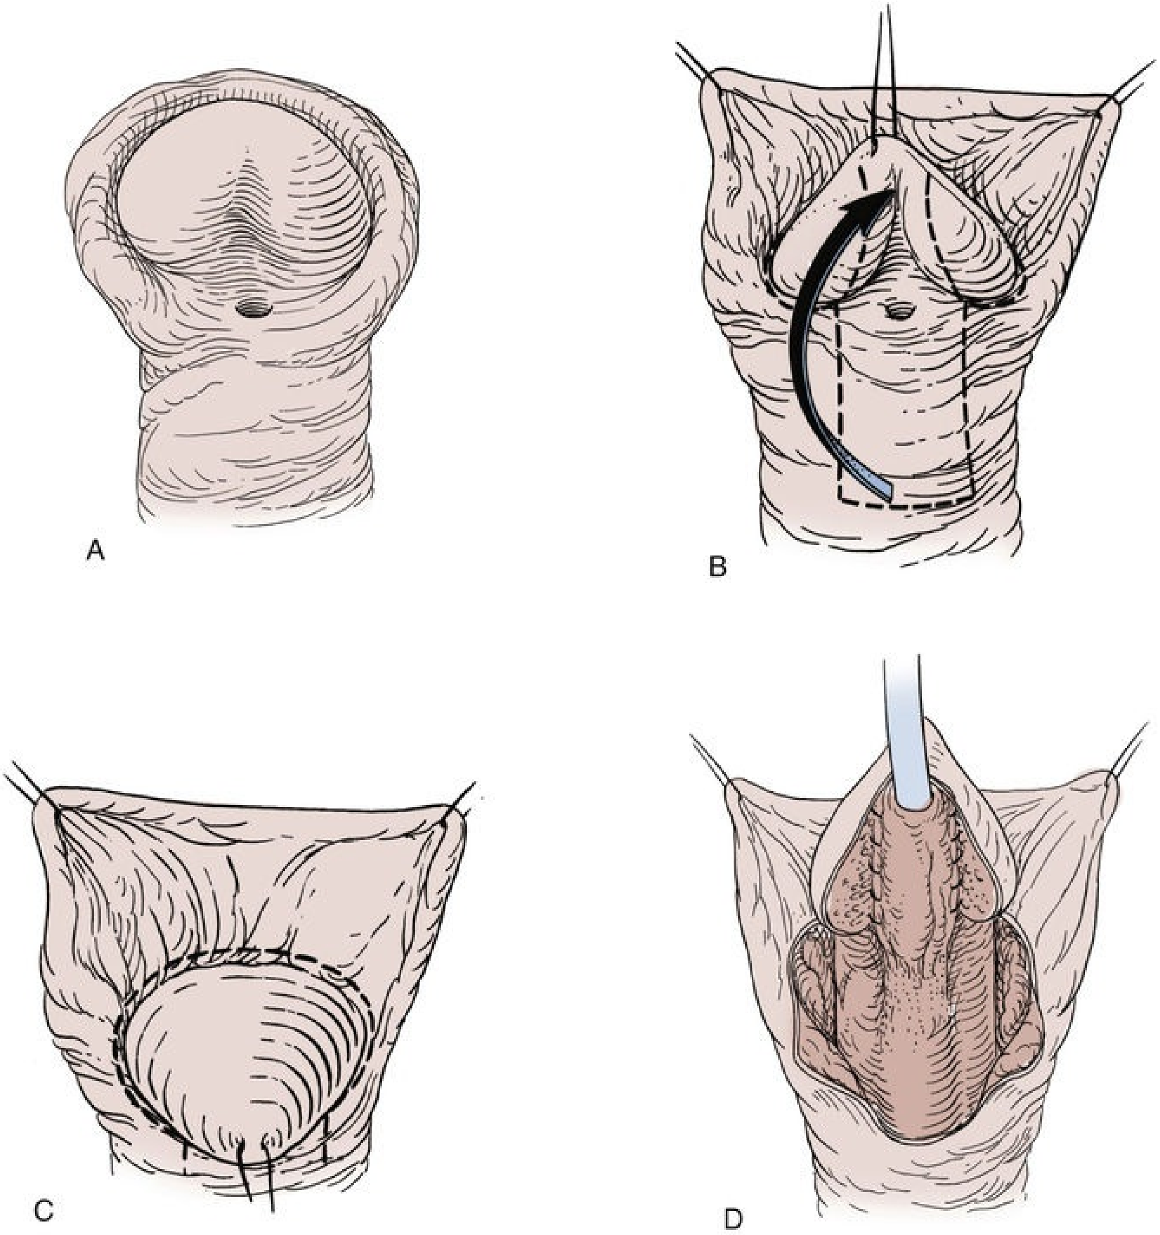

FIG. 45.19 (A,B) Parameatal skin flap is marked and incised. Incisions are extending into the glans. (C) Circumscribing incision is made. (D) Meatal flap is "flipped" onto the urethral plate, with a running suture line running parallel to either side of the late. Once the urethra is closed, glansplasty is performed.

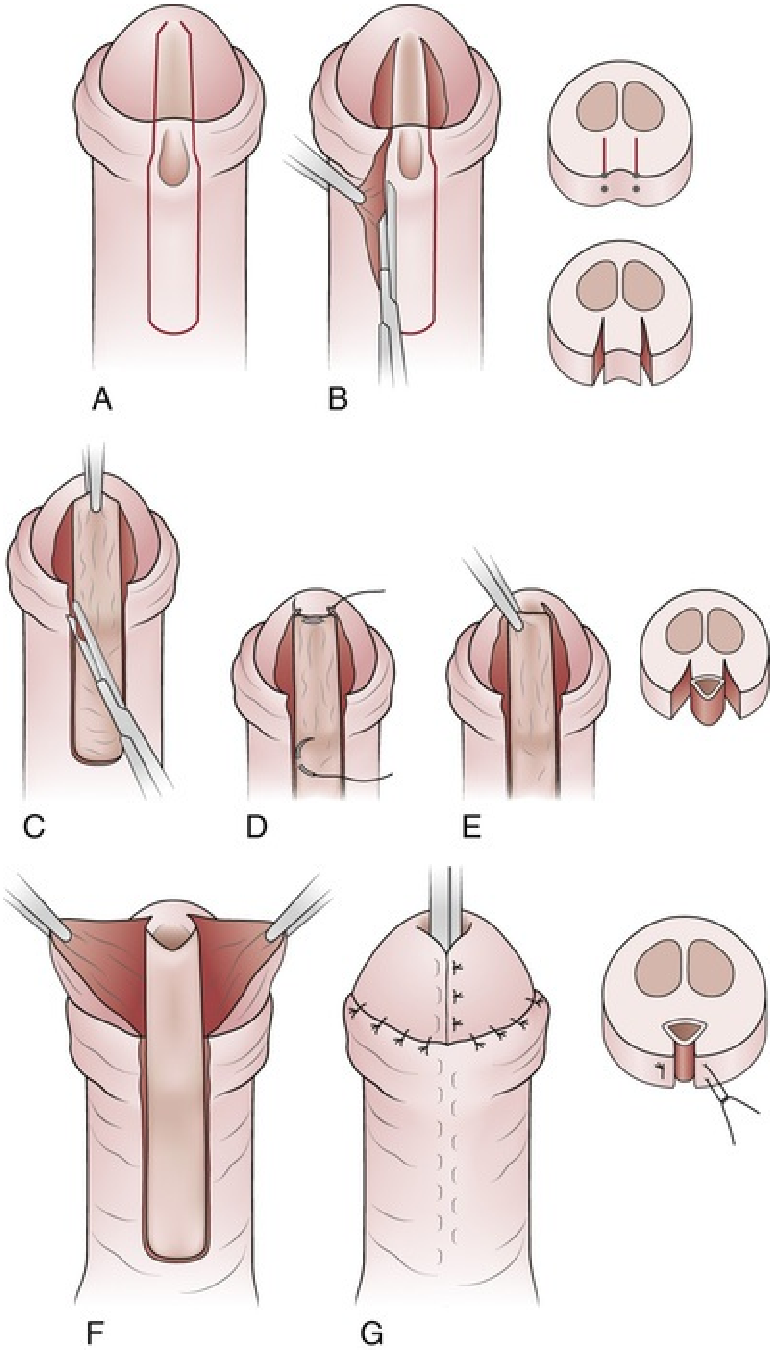

FIG. 45.20 The slitlike adjusted Mathieu (SLAM) technique. (A) A U-shaped incision is marked on the ventral penile shaft. Within the glans, the incisions are made parallel to each other and long the true urethral plate to develop proper glans wings. Proximally, the incisions diverge to create a wide-based flap. (B,C) The flap is mobilized, taking care to preserve spongiosal tissue on the flap. (D) The edges of the flap are sutured in place on either side of the urethral plate. (E) V-shaped excision of the flap is performed to achieve a slitlike meatus. (F,G) Glansplasty is performed. (From Hadidi AT: The slit-like adjusted Mathieu technique for distal hypospadias. *J Pediatr Surg* 47[3]:617–623, 2012.)

The onlay island flap (OIF) procedure is particularly useful in the setting of a narrow urethral plate. To augment the plate, an island flap of dorsal inner preputial skin is harvested, transposed ventrally, and sutured onto the plate to close the urethral defect (Fig. 45.21). Although a popular repair in the 1990s, after introduction of the simpler TIP procedure, this repair fell out of favor except in a few centers. Many surgeons complain that they have difficulty harvesting a consistent flap that will not develop a diverticulum. **We have found that a vertical incision on the ventrum of the penile shaft to the penoscrotal junction facilitates flattening of the dorsal shaft skin, which makes the blood supply to the flap more evident.** The actual harvest begins dorsally at the penopubic junction and progresses distally. This approach facilitates the procurement of a consistent flap. Concerns for this approach compared with the TD or TIP procedures include a fish-mouth or rounded meatus as compared with a more cosmetic oval contour with the TD and/or TIP unless Rich's modification is employed (Rich et al., 1989). After the OIF procedure, these boys are at higher risk for development of a urethral diverticulum because of the elasticity of the inner preputial skin present in the island flap. On the other hand, our impression is that meatal or urethral stenosis is less common in this repair.

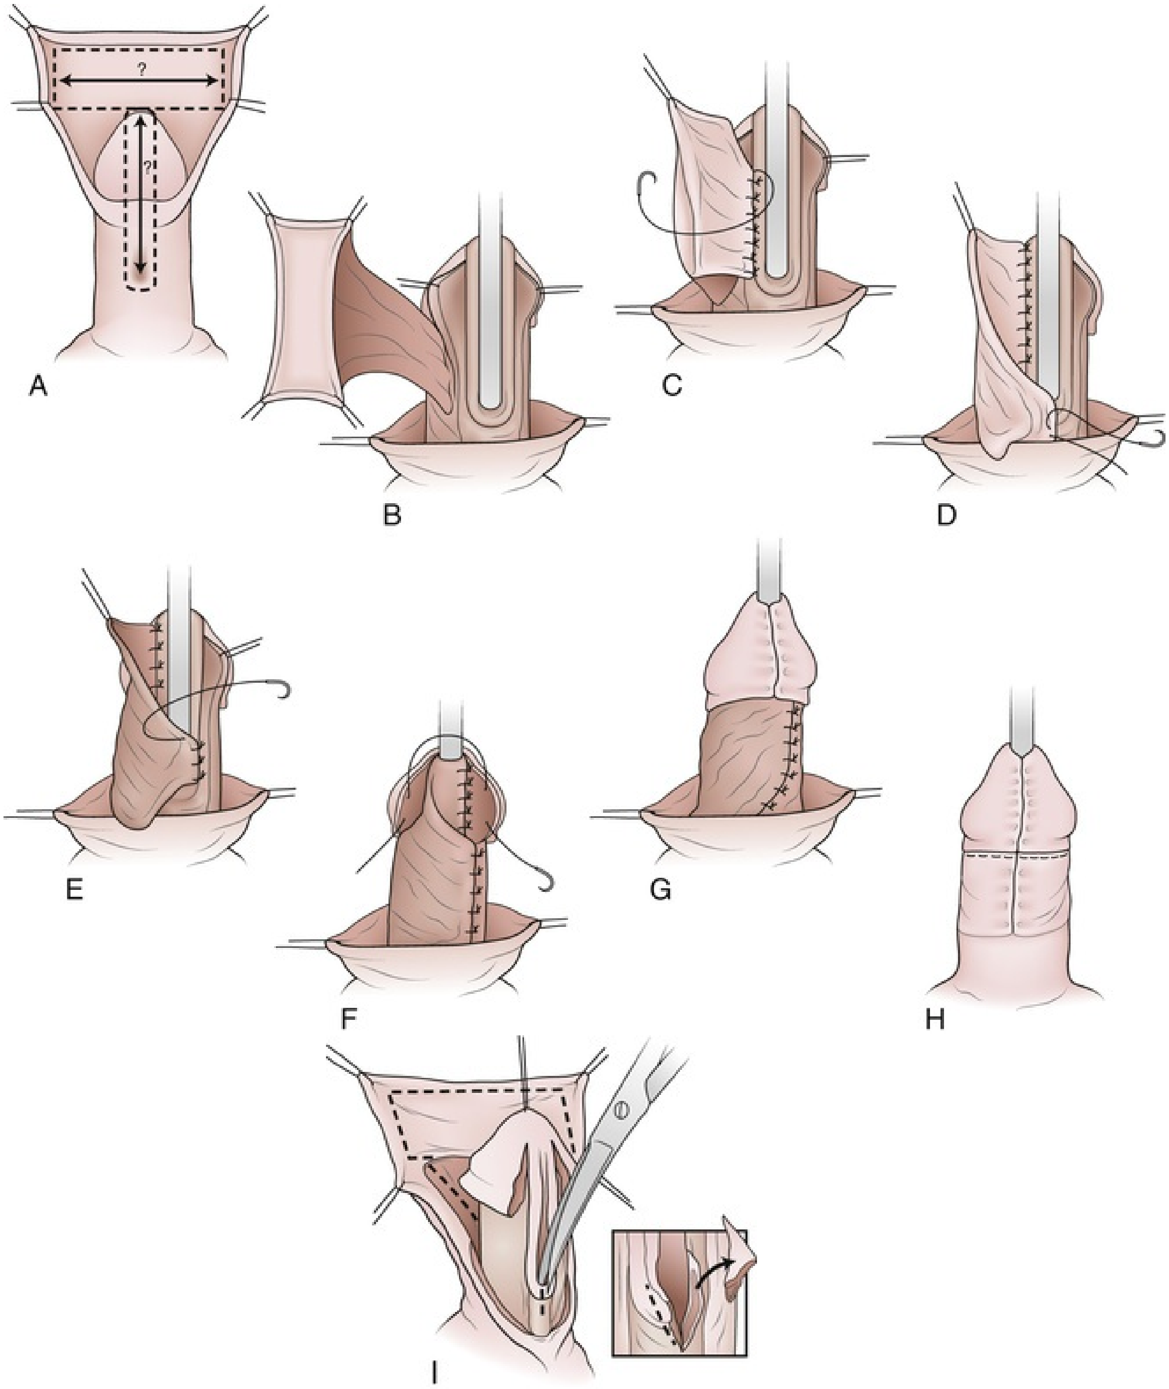

FIG. 45.21 The onlay island flap (OIF) technique. (A) Planned incisions to harvest transverse preputial flap and urethral plate. (B) Isolation of preputial flap on vascularized pedicle. *Inset,* Preparation of meatus for anastomosis, including excision of stenotic or hypoplastic meatal tissue. (C) Initiation of anastomosis of onlay flap and urethral plate. (D) Proximal approximation at the native urethra. (E) Completion of the neourethra channel. (F) Application of second layer of barrier coverage. (G–I) Glansplasty and skin closure.

Key Point

- Many options exist for distal hypospadias repair, many of which are technical variants of each other. Surgeons should use a technique that they feel comfortable with and yields a high success rate.

Proximal Hypospadias

Our appreciation for the importance of careful surgical treatment of curvature has driven a dramatic evolution in our approach to the management of proximal hypospadias. Concerns for recurrence of penile curvature in severe hypospadias when managed with dorsal plication alone have shifted the pendulum toward more aggressive corporal lengthening procedures, and therefore, in the hands of most surgeons, a multistage repair.

One-Stage Hypospadias Repair

In general, the one-stage proximal hypospadias repair involves dorsal plication to correct ventral penile curvature in conjunction with several different urethroplasty techniques. These can be stratified according to the tissue used in the repair, specifically preputial skin versus local skin versus buccal graft.

In 1980 Duckett harvested a preputial island flap, tubularized it into a substitution urethroplasty, and created what is called a transverse preputial island flap (TPIF) or the Duckett tube (Fig. 45.22). We have since modified the technique from its original description (Asopa et al., 1971; ▶Video 45.9). **Rather than tubularizing the flap before securing it to the penile shaft, we now anchor the left side of the flap to the ventral surface of the penile shaft, just to the left of midline. The flap is then closed in the midline, with interrupted Lembert sutures to reduce the risk of exposing epithelium beneath the repair. Both rows of sutures are carried into the midglans. The pedicle of the flap is carefully placed over the suture line. The glans wings are then brought over the urethroplasty and vascular flap. This approach anchors the base of the tubularized flap to the distal extent of the native urethra** (Fig. 45.22E). This provides a point of tension that will guide the subsequent tubularization along the longitudinal axis of the neourethra, removing laxity to reduce the risk of diverticulum development. The tube is closed in a two-layer fashion, maintaining an even caliber throughout its course (Fig. 45.22F). This approach is applicable in the circumstance when the curvature is severe but corrected after skin dissection and division of the urethral plate. **The amount of tissue placed within the glans can hamper glans closure and result in an oval appearance to the meatus, as opposed to a slitlike meatus seen with other repairs, limiting its use.** A higher complication rate with the TPIF resulted in Duckett preferentially using the OIF procedure, even for severe hypospadias (Duckett, 1995).

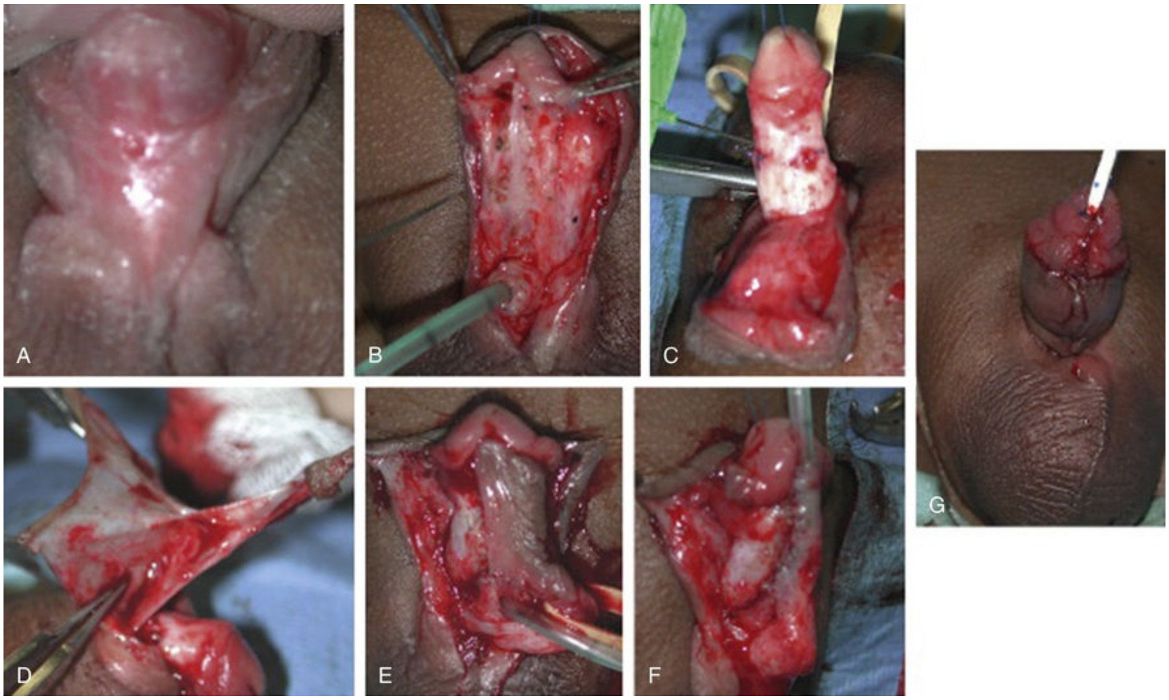

FIG. 45.22 Island tube hypospadias repair. (A) Preoperative appearance. The pink, shiny, ventral skin suggests a thinning of the ventral spongiosum. In spite of the subcoronal meatus, this is a proximal variant. Incisions are marked and made in a similar fashion according to the schematic in Fig. 45.21. (B) After degloving the meatus is located at the penoscrotal junction and is cannulated with an 8-Fr feeding tube. (C) Artificial erection after dorsal plication reveals no residual penile curvature. (D) The preputial island flap is mobilized, with harvest of the supple dartos pedicle off of the shaft skin toward the base of the penis. (E) One edge of the flap is anchored to the tunica albuginea. (F) The flap is measured to a width of 12 mm with excision of redundant epithelium. The flap is then closed over a diversion tube, approximating the epithelial edge to the previously anchored portion of the flap. (G) Completed repair. (From Kraft KH, Shukla AR, Canning DA: Hypospadias. *Urol Clin North Am* 37[2]:167–181, 2010.)

The OIF procedure was described in the previous section for distal hypospadias but evolved from Duckett's experience with the TPIF (see Fig. 45.22). It is a versatile technique and can be used for more proximal variants. **Indications include boys whose curvature is corrected after penile degloving and does not require division of a relatively thin urethral plate that otherwise could not be tubularized. Although at one point used at CHOP in more than 90% of hypospadias repairs, it has since been replaced by other procedures for severe hypospadias and is now most commonly used for midshaft hypospadias repair in which release of skin and division of urethral plate results in correction of curvature.**

Technical aspects of the repair are reviewed in Figs. 45.21 and 45.22. After degloving, incisions along the urethral plate are made in parallel through the glans (see Fig. 45.22A, Video 45.8). Dorsal skin dissection should be in the avascular plane above Buck fascia, preserving the vascular pedicle to the preputial skin. The preputial skin flap is marked with stay sutures (see Fig. 45.22B), then transposed ventrally to align over and to the urethral plate with a full-thickness suture (see Fig. 45.21C). The native urethral meatus is spatulated (see Fig. 45.21). The combined width of the urethral plate and flap should be 12 mm or less, and is trimmed accordingly, in particular to narrow the proximal flap to prevent a diverticulum at the junction of the neo and native urethral anastomosis (see Fig. 45.21D). The remainder of the anastomosis is completed in a running or interrupted Lembert fashion (see Fig. 45.21E).

The TIP repair was previously described in the distal hypospadias section. Extension of this technique to more severe hypospadias was described, particularly in the setting of a boy whose curvature is corrected with skin dissection or plication in combination with an adequate urethral plate (Fig. 45.23; Snodgrass and Lorenzo, 2002). Technical modifications including urethral plate mobilization and transverse corporotomies, in the setting of persistent ventral curvature of greater than 30 degrees after degloving, were proposed to increase the applicability of the TIP for proximal hypospadias (Snodgrass and Bush, 2011). **Subsequent analysis by Snodgrass et al.** (2013) **suggests that aggressive mobilization of the urethral plate leads to devascularization, increasing the risk of stricture formation, which ultimately limits the applicability of proximal TIP in this setting. Because of a higher risk of complications, this technique has since fallen out of favor for other two-stage repairs, such as the Byars flap or STAG repair.**

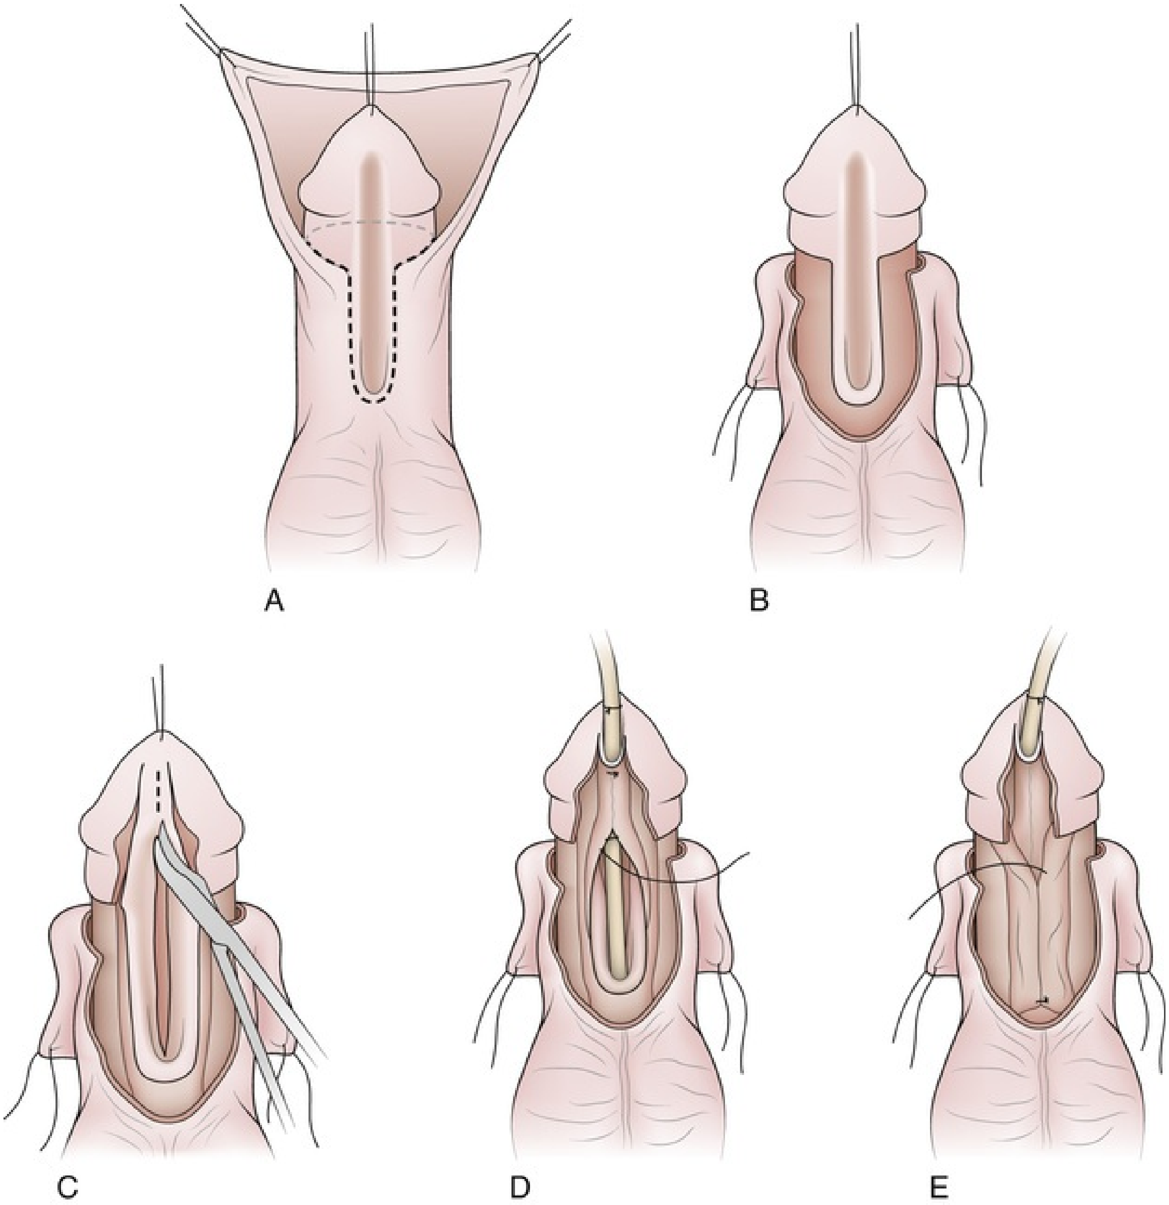

FIG. 45.23 Proximal tubularized incised plate (TIP) repair. (A) Circumscribing incision preserved urethral plate. (B) After degloving, the surgeon separates the glans wings from the urethral plate. Corpus spongiosum is dissected from the cavernosal bodies and released distally from the glans wings for later spongioplasty. Artificial erection is performed, and if curvature is less than 30 degrees and corrected with plication, TIP procedure can be considered. (C) Midline urethral plate incision, extended to the level of the corporal bodies. (D) Two-layer urethral plate tubularization using interrupted subepithelial 7-0 polyglactin suture. (E) Spongioplasty approximates divergent corpus spongiosum over the neourethra before a tunica vaginalis barrier flap is added. (Modified from Snodgrass WT: Snodgrass technique for hypospadias repair. *BJU Int* 95:683–693, 2005.)

The reasoning behind the current trend toward a staged repair for severe hypospadias, in which the curvature is corrected at the first stage and urethroplasty is performed at the second stage, lies with the methods used to correct curvature and while providing supple ventral shaft tissue for tubularization. Concerns for a higher risk of urethroplasty failure when combined with a corporal grafting procedure in a single-stage repair have led to this paradigm shift (Castellan et al., 2011; Mattos et al., 2016). Alternatively, although rarely performed, a corporal lengthening procedure may be combined with urethral closure in a single-stage repair. This is achieved through use of a flap corporoplasty, in contrast to a free graft, which could theoretically prevent contracture and facilitate healing of the overlying urethroplasty. Braga et al. (2007b) reported their approach with simultaneous tunica vaginalis flap for corporal lengthening with subsequent urethroplasty with TPIF to complete the repair in a single operation.

Two-Stage Hypospadias Repair

As the management of severe ventral penile curvature has migrated toward corporal lengthening procedures, the two-stage repair has emerged as the approach of choice for the majority of surgeons in management of proximal hypospadias. Although many technical variations exist, modern two-stage approaches can be divided into three main categories, each separated by fundamental differences to the approach to urethroplasty (Videos 45.1 and 45.10).

Two-Stage Repair With Free Graft

The Bracka two-stage repair uses a free graft, harvested from either the inner preputial skin or buccal mucosa, as a template for urethroplasty (Fig. 45.24; Altarac et al., 2012; Bracka, 1995). **The staged tubularized autograft (STAG) repair is a modification of Bracka's original description** (Pippi Salle et al., 2016; Snodgrass and Bush, 2017a; Fig. 45.25). In the first stage, penile curvature is corrected and the urethral plate is divided**. A midline incision is extended into the glans to act as a receiving bed for the graft. A compression dressing and quilting of the graft into place on the ventral penile shaft can prevent hematoma formation and facilitate graft take.** The second stage is performed at least 6 months later, in which a U-shaped incision, similar to the Thiersch-Duplay approach, is made and the urethra is tubularized and glansplasty is performed (Bracka, 1995). Multilayer closure is performed to maintain vascular flow to aid the healing process. **This technique has since been modified by incorporation of multiple ventral corporotomies, without subsequent graft coverage, as a corporal lengthening procedure. Proximal urethral mobilization and a more extensive glans dissection have also been used to improve the repair** (Pippi Salle et al., 2016; Snodgrass and Bush, 2017a). Caution must be taken when placing a free graft directly over the corporotomies as graft contracture can occur.

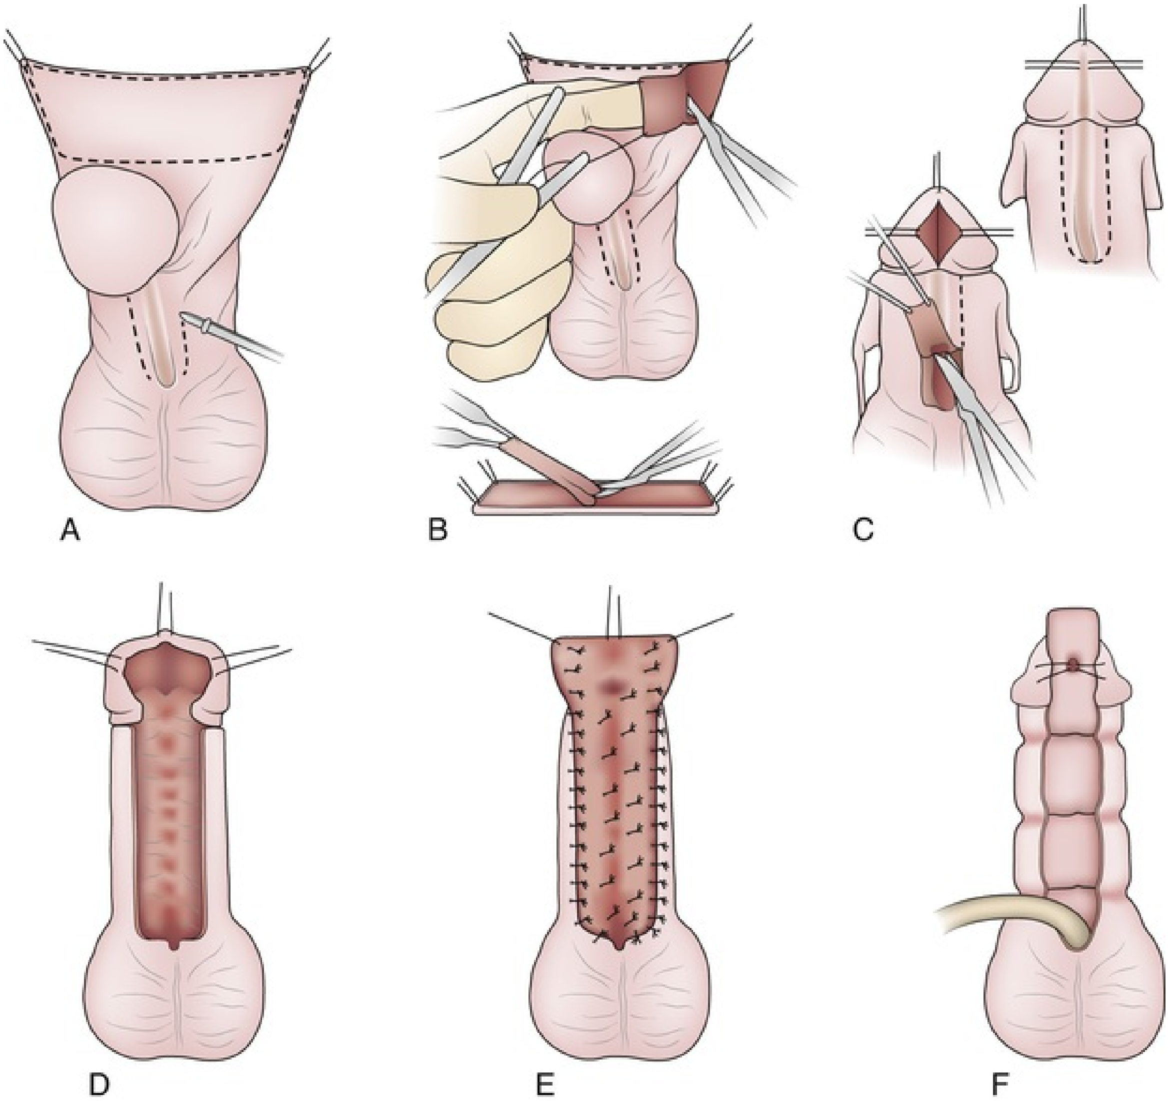

FIG. 45.24 Bracka two-stage free graft repair. (A,B) Inner preputial free graft incision is marked and harvested. (C) Abnormal urethral plate is excised and penis is degloved. (D) Incision is extended into the glans, mobilizing glans wings. (E) Preputial graft is secured into place, including

quilting sutures. (F) Compression dressing is sutured into place over the graft. (Modified from Altarac S, Papeš D, Bracka A: Two-stage hypospadias repair with inner preputial layer Wolfe graft. *BJU Int* 110:460–473, 2012.)

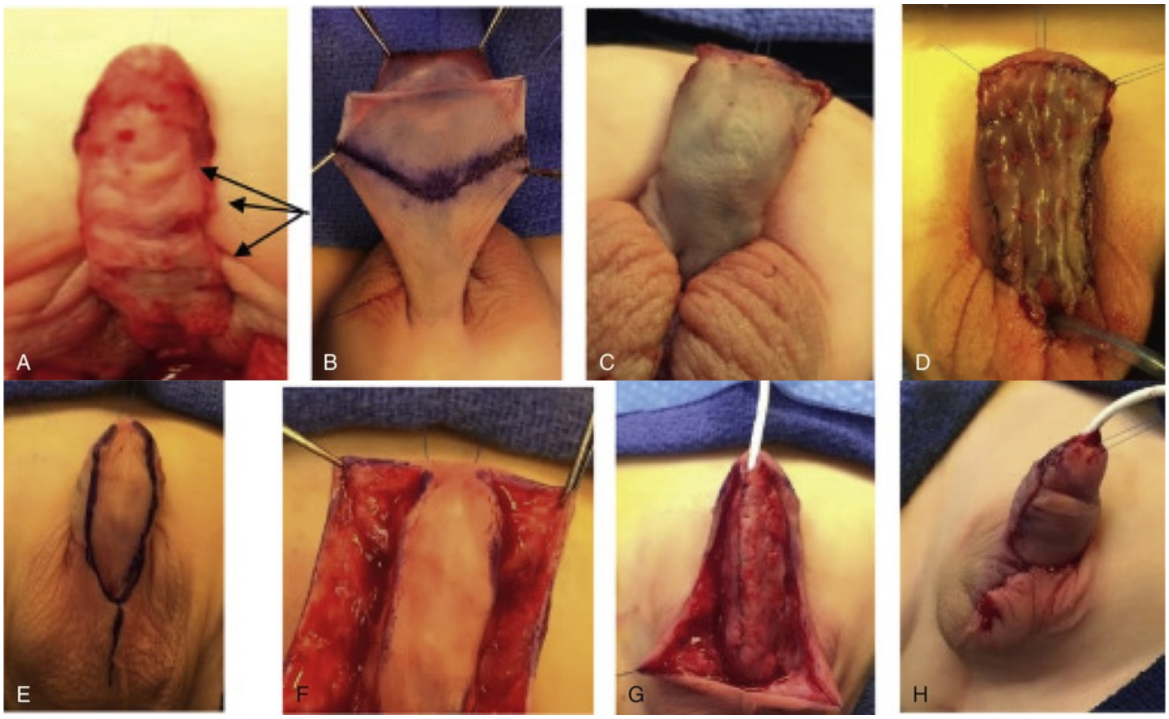

FIG. 45.25 The staged tubularized autograft (STAG) repair. (A) At the time of the first stage, one to three ventral corporotomies are made through the tunica albuginea, with the middle incision opposite the point of maximal curvature. (B) Preputial graft is marked and harvested. (C) Preputial graft is placed on the ventral aspect of the penile shaft and then quilted into place (D). The bottom panel displays the second stage of the repair. (E) Urethroplasty incisions are marked and extended along the midline of the scrotum. (F) Glans wings are developed. (G) Two-layer urethroplasty is performed and subsequently covered with a barrier layer with tunica vaginalis. (H) Appearance after closure. (From Snodgrass W: Staged tubularized autograft repair for primary proximal hypospadias. *J Urol* 198:680–686, 2017.)

Two-Stage Repair With Pedicle Flap

The Byars flap procedure uses redundant dorsal preputial skin, which is transposed ventrally with its vascular pedicle at the first procedure, as the scaffold to form the urethra (Fig. 45.26; Byars, 1951; Retik et al., 1994). The skin can be joined in the midline on the ventral aspect of the penis (Fig. 45.26F) or can be aligned as a single unit as used for the STAG repair (Fig. 45.25; Video 45.11). At the second stage the neourethra is closed by making a long U-shaped incision with glansplasty using a standard Thiersch-Duplay technique. **Some key technical components include creation of a watertight, two-layer closure and establishing a lumen of equal caliber throughout the length of the urethroplasty. Multiple layers of closure are required to ensure that the neourethra maintains adequate blood supply. In particular, establishing a supple dartos bed overlying the corporoplasty at the first stage will provide sufficient vascular flow to allow safe urethroplasty at the second stage** (Video 45.10).

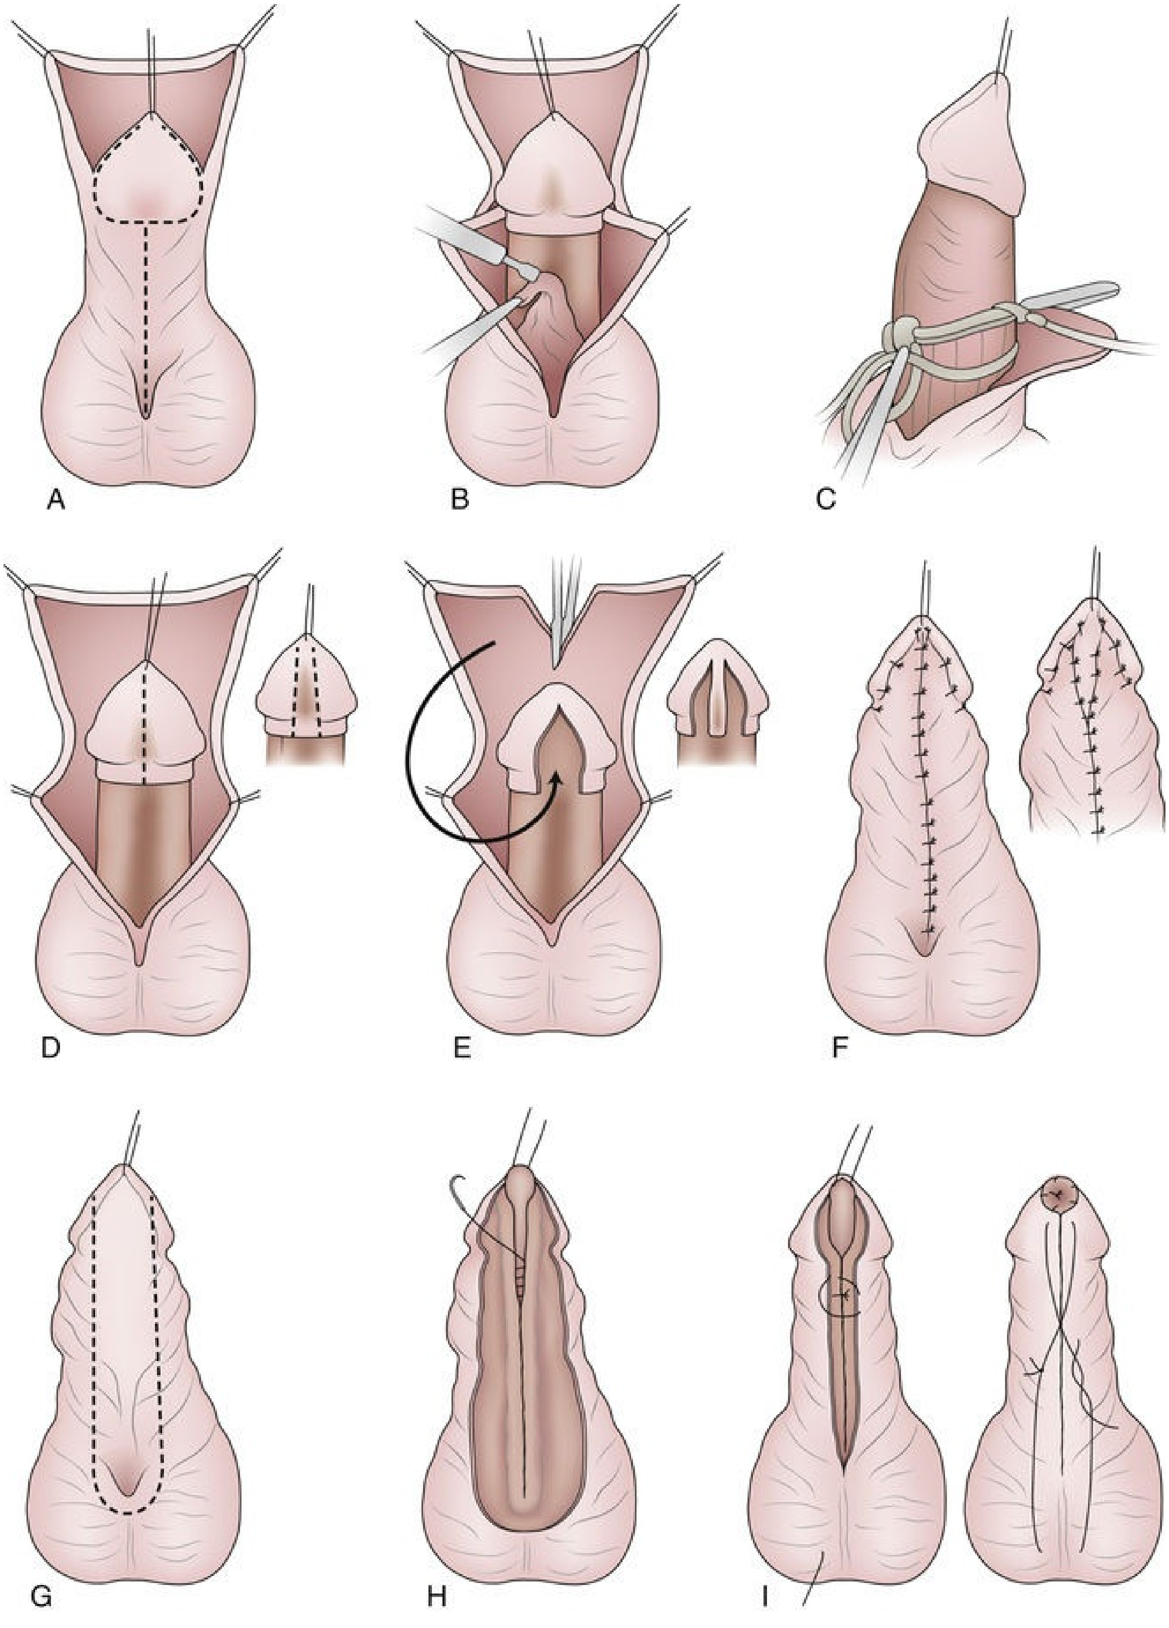

FIG. 45.26 Two-stage hypospadias repair with Byars flap. (A) First stage:

incisions are marked to allow degloving and mobilization of ventral skin. (B) The penis is degloved to the penoscrotal junction. Any dysplastic, or chordee, tissue is removed. (C) Artificial erection to assess penile curvature. For the purpose of the illustration the curvature has already been corrected. (D) Either midline or parallel lateral glans *(inset)* incision(s) is (are) made in the glans and glans wings developed. (E) Byars flaps are developed by incising the dorsal inner preputial skin in the midline to the mucosal collar, yielding a proper skin fit dorsally. (F) The redundant dorsal skin is transposed ventrally and secured in place. (G) Second stage: a U-shaped Thiersch-Duplay incision is made for tubularization. (H) Urethroplasty is performed, either in an interrupted or running fashion, using a two-layer technique. Additional barrier layer with dartos or tunica vaginalis can be performed. (I) Glans and shaft skin are approximated.

The third approach involves correction of the penile curvature with simultaneous closure of the distal urethra and glans at the first stage of the repair. An interposition flap or graft replaces the deficient urethra at the first-stage repair, and the patient is left with a proximal functional meatus after the first procedure. The second stage of the repair involves urethroplasty to close the proximal urethra, joining it with the previously closed distal urethra. One variant of this approach uses a TIP type of distal closure for the urethra and glans in the first stage (Cheng et al., 2003). Alternatively, the Ulaanbaatar repair creates a transverse island interposition tube, which is tunneled into the distal portion of the glans (Dewan et al., 2004; Jayanthi et al., 2017; Fig. 45.27).

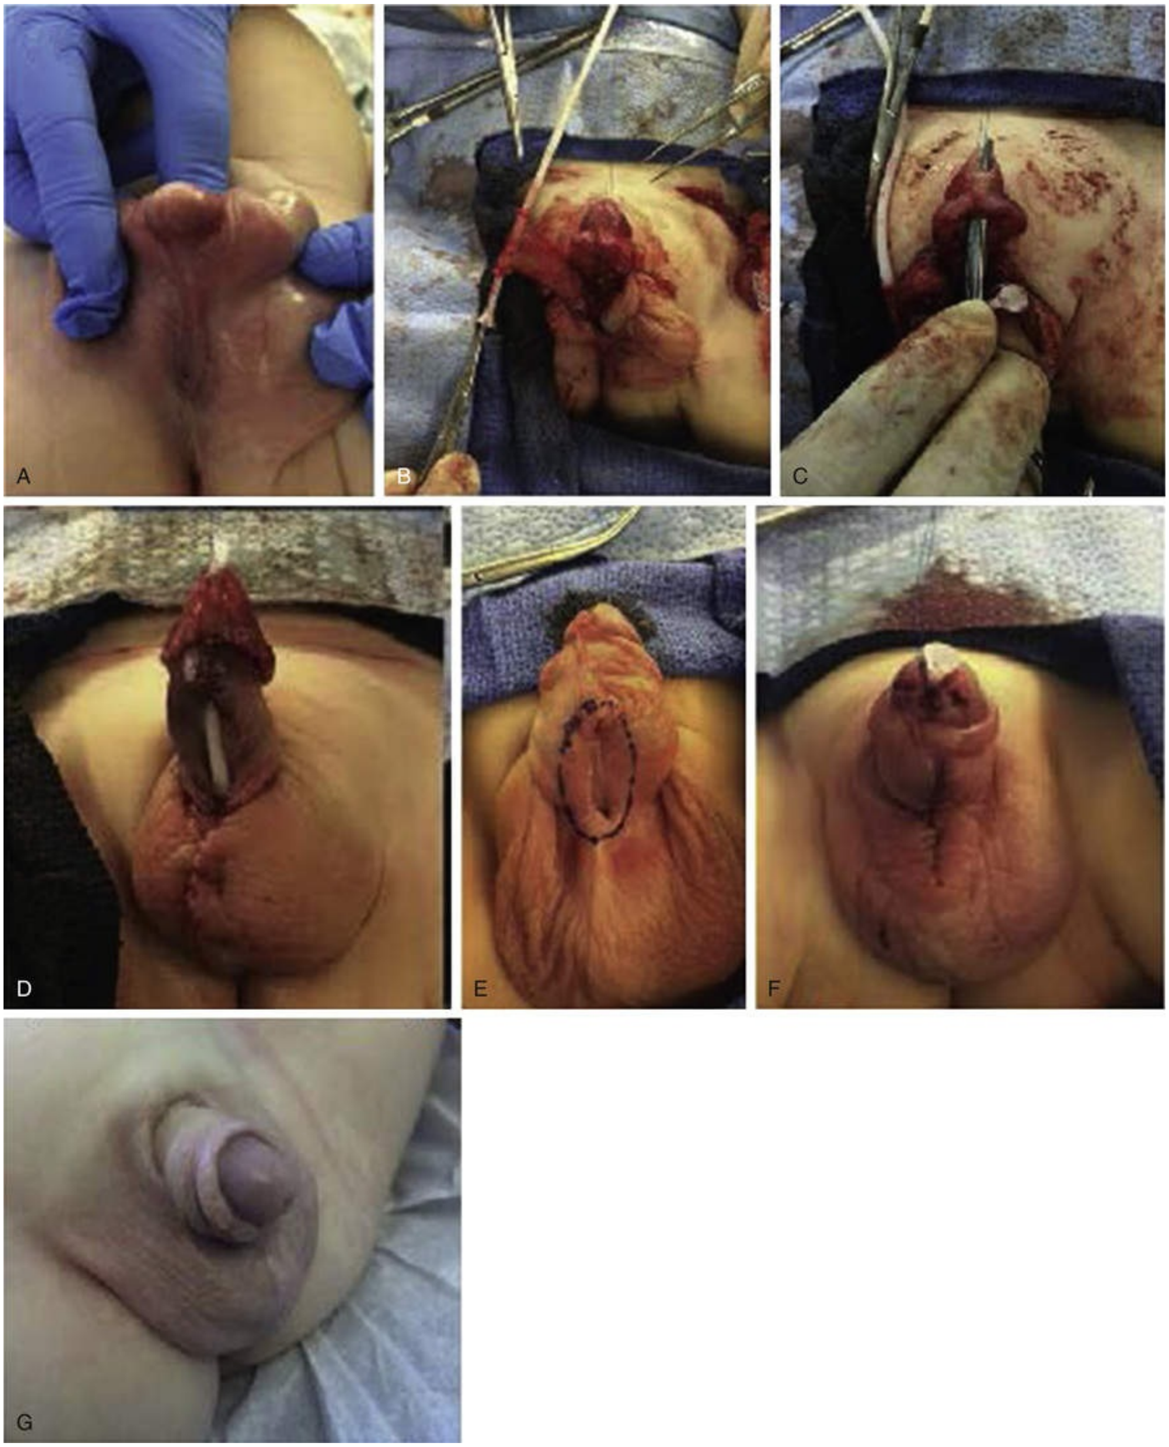

FIG. 45.27 The modified Ulaanbaatar staged hypospadias repair. (A) Initial appearance of the penis before incision. This patient had 46,XY ovotesticular disorder of sexual differentiation, severe ventral penile curvature, and a proximal hypospadias. Incisions are made and curvature is corrected with small intestinal submucosa during the first stage of the operation. (B) A transverse island tube Duckett tube is harvested for a

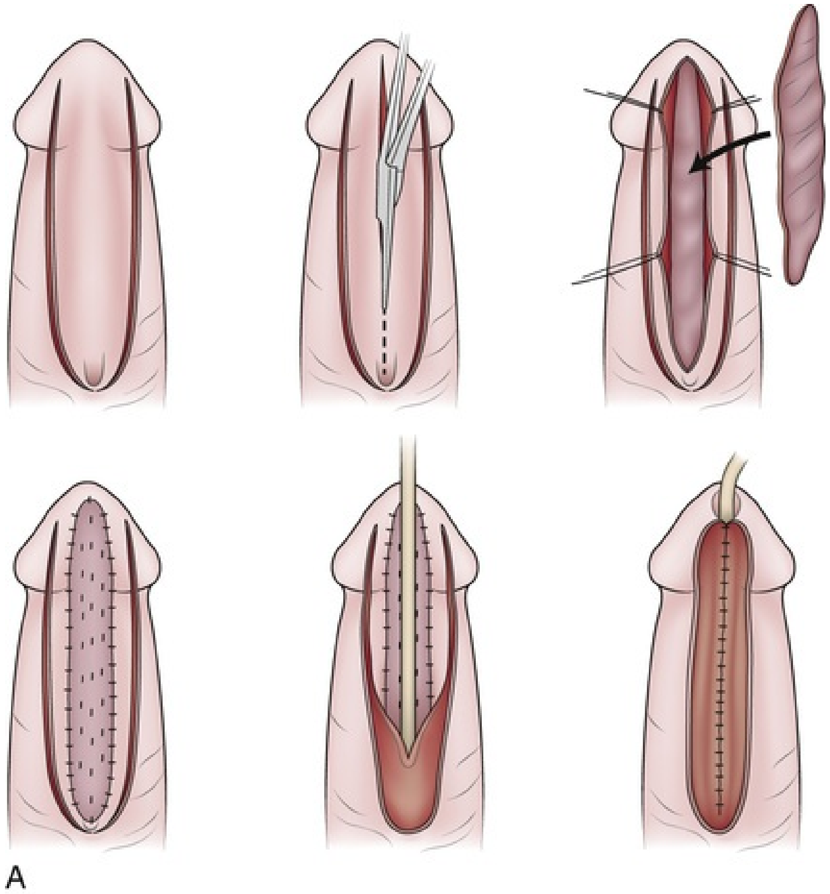
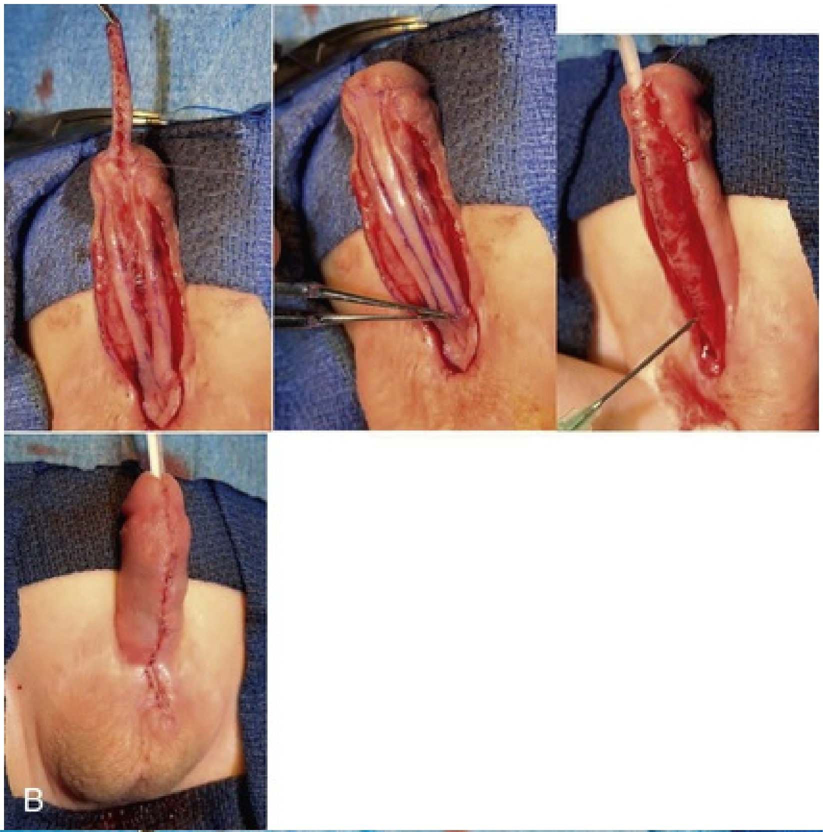
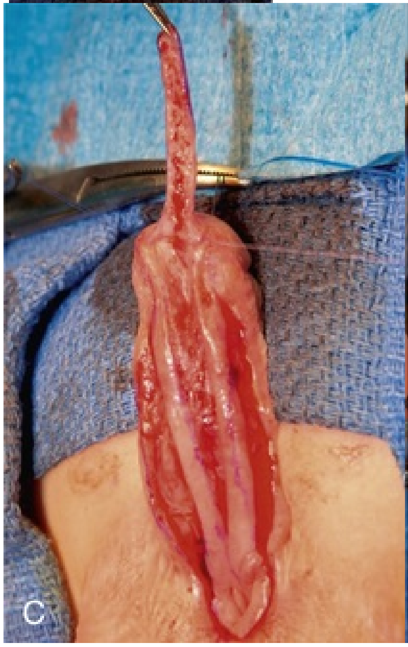
length that will replace the glanular and distal penile urethra. (C) The neourethra is either tunneled into the glans (if of sufficient size) or a formal glans incision with glansplasty is performed. (D) Byars flaps are rotated ventrally to replace the gap in the urethra between the proximal end of the Duckett tube and the distal extent of the native urethra. A drip stent is left in the closure. (E) After an interval 6 months, an elliptical incision is made around the urethral defect and tubularized. (F,G) The appearance after closure and 3 months postoperatively. (From Jayanthi VR: The modified Ulaanbaatar procedure. *J Pediatr Urol* 13(4): 353, 2017.)

Regardless of the approach, it is important to assess the quality of graft or flap take at the second stage of the repair. In the scenario in which there is skin deficiency or tethering precluding safe closure, an intermediary step of a dorsal inlay buccal mucosal graft may be used (Kolon and Gonzales, 2000) (▶Video 45.12)**. After graft take, the urethra is then reconstructed at a later date when all of the tissues are supple.** Alternatively, a dorsal buccal graft inlay and same-stage urethroplasty may be done at the time of the second-stage repair (Fig. 45.28).

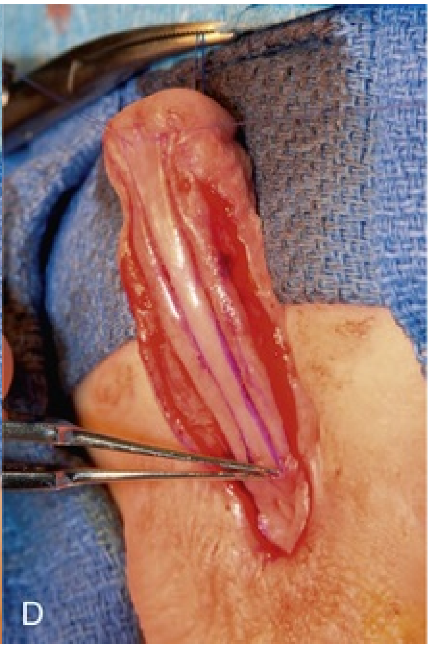




B



C



D

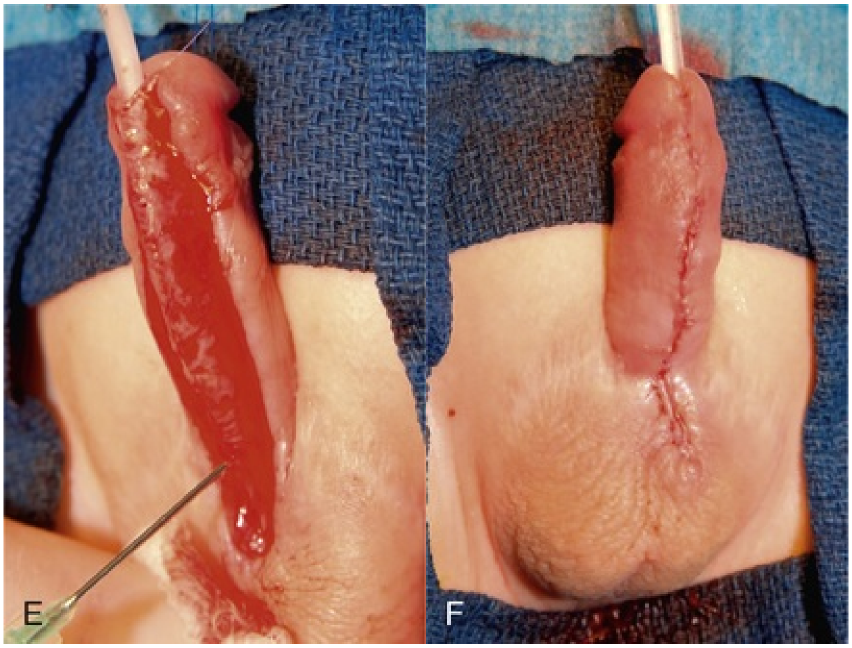


FIG. 45.28 Illustration (A) and live surgery pictures (A–F) depicting a single-stage buccal inlay graft. The penis is assessed and the urethral plate is found to be too narrow for primary tubularization. A U-shaped incision for a Thiersch-Duplay repair is made. A midline incision is made within the future urethral plate and a buccal graft is secured into the midline. Urethroplasty is then performed according to the width of the edges of the initial U-incision. Additional layers of closure are added as a barrier layer and the penis is closed. The final live surgical image represents the closed penis appearance. (Images courtesy Rafael Gosalbez, MD.)

Regardless of the approach to proximal hypospadias repair, it is important to confirm that penile curvature is corrected with repeat artificial erection at the time of the second operation before urethroplasty. If necessary a dorsal plication can be performed to correct minor recurrent curvature or a repeat corporal lengthening procedure if warranted. **A waiting period of at least 6 months should occur between procedures to ensure proper graft and/or flap incorporation and neovascularization.** We often allow 8 to 12 months between procedures, with interval exams to ensure satisfactory graft/flap incorporation, to monitor for recurrent curvature, and to determine if the ventral skin is supple enough to achieve satisfactory urethroplasty.

Comments on Proximal Hypospadias Repair

Analysis of the published literature reveals a recent focus on high complications for proximal hypospadias. Historical data likely

underestimate the complication rate by grouping mild and severe variants, artificially decreasing the understood complication rate for isolated proximal hypospadias (Long and Canning, 2016a). The contemporary rate for needing additional procedures after a planned two-stage repair ranges from 25% to 75%, and additional procedures put these boys at further risk for further complications. As a specialty, although we are effectively correcting 80% of boys who have distal hypospadias, we must direct more efforts to reduce complications in proximal hypospadias.

Why are proximal repairs harder? One reason may be the longer urethroplasty required to repair a proximal hypospadias. This increased length is more technically demanding, requiring precise technique to generate a long urethra of equal caliber throughout its course. One unanswered question is whether the neourethra, from whatever tissue is chosen for reconstruction, is inherently narrowed as a result of reconstruction, limiting its ability for gentle yet repeated expansion to propel the urine bolus as a normal urethra would.

A longer neourethra may more dramatically demonstrate the physics behind laminar flow and fluid dynamics. **According to Poiseuille's law the resistance to flow in a cylinder is proportional to the length of the tube but is inversely proportional to the radius to the fourth power** (Fig. 45.29)**. In plain terms the pressure required to push urine through the lumen of the urethra directly increases with the length of the tube. At the same time minor variations to the radius, either increasing or decreasing in size, will have a much greater impact upon intraluminal pressure. The longer the tube, the greater the risk for stricture. The failure of the reconstructed urethra to expand with voiding increases resistance to urine flow, ultimately resulting in fistula and/or urethral diverticulum formation** (Braga et al., 2007a). In addition, the glans is relatively nondistensible because of densely packed spongiosum tissue. Hence even in situations in which the neourethral lumen is exactly the same caliber throughout, diverticulum formation is a significant risk because of a fixed distal urethra. The penile urethra may distend nicely, but when the urine reaches the glans, poor distention increases turbulent flow, resulting in increased pressure of the proximal urethra and diverticulum development.

FIG. 45.29 Comparison of the urethral resistance and flow patterns for the tubularized incised plate (TIP) repair (A,B) vs. onlay procedure. To the left of the illustration is a corresponding uroflow. All three diagrams assume a patent urethral meatus. (B) The short neourethral length provides a small amount of resistance over a narrow distance, resulting in a relatively normal flow pattern. This is in contrast to (A), where the long TIP repair provides a fixed amount of resistance across a much longer distance. This results in a prolonged void with a dampened velocity. (C) The increased elasticity of the tissue used in the onlay procedure decreases the resistance of the neourethra, allowing a more normal voiding pattern. The fundamental differences between these two repairs are due to the more rigid urethra created with the TIP repair versus the more pliable tissue used in an onlay procedure. (From Braga LP, Pippi Salle JL, Lorenzo AJ, et al: Comparative analysis of TIP versus onlay island flap urethroplasty for penoscrotal hypospadias. *J Urol* 178:1451–1457, 2007.)

It is also possible that the degree of tissue dysplasia, severity of penile curvature, and relative lack of skin may compromise wound healing, compromise vascular flow, or prevent equal tissue growth with time as the boy ages. Given the relatively small number of patients with proximal hypospadias across the world and the increasing number of pediatric urologists performing these procedures, the number of surgeries performed by most surgeons is decreasing. Collaboration is going to be vital for our field to increase patient numbers to provide a measurable advancement in the care of boys with these complex challenges.

Key Points

- Proximal hypospadias has a higher complication rate than distal repairs and represents a unique challenge to the urologist.
- The reasoning behind the current trend toward a staged repair for severe hypospadias, in which the curvature is corrected at the first stage and urethroplasty is performed at the second stage, lies with the methods used to correct curvature and while providing supple ventral shaft tissue for tubularization. Concerns for a higher risk of urethroplasty failure when combined with a corporal grafting procedure in a single-stage repair have led to this paradigm shift.

Postoperative Management

Proper postoperative care is essential. Even a well-planned and technically excellent surgical repair can be compromised with careless postoperative management. Options for methods of urinary diversion, dressings, and perioperative medication administration have varied greatly throughout the history of hypospadias management. Unfortunately, quality data proving a direct influence on outcomes are lacking. During the first 48 hours after surgery, urinary diversion and a compressive dressing are employed by the surgeon. The dressing is designed to minimize stress on the freshly closed neourethra, tamponade bleeding, and minimize swelling. **For complicated repairs, urinary diversion with a soft, pliable urethral stent decreases rates of meatal stenosis and urethrocutaneous fistula development** (Daher et al., 2015; Hakim et al., 1996). In our practice a compressive dressing is left for a 72-hour period, after which petroleum jelly is applied to facilitate healing. A suprapubic tube may be placed, particularly in older children or in redo cases, to maximize urinary diversion.

Urinary diversion is provided for a period of 3 to 21 days and varies according to the complexity of the repair, the length of the urethroplasty, and surgeon preference. In one study, prolonged stent duration has been shown to decrease complication rates (Daher et al., 2015). This finding is not universally accepted. Stent duration must be weighed against patient discomfort and the risk for UTI, which increases with each day of diversion. Some surgeons have performed distal repairs of a short urethroplasty length without a urethral stent without any change in outcomes (Steckler and Zaontz, 1997). Antibiotic prophylaxis is frequently administered, as previously discussed. **Postoperatively, bladder spasm is common and can result in high-pressure voiding around stents and catheters, placing undue stress on the urethroplasty. This can be alleviated with the addition of oxybutynin until stent removal. Longer and stiffer stents that extend well beyond the neomeatus may place undue pressure on the ventral urethral repair, increasing the risk for glanular dehiscence.** A Foley catheter, if placed, must be secured to the anterior abdominal wall in the midline to prevent glans separation. **Unfortunately, these catheters frequently end up with undue lateral or ventral tension from the securing tape releasing prematurely.** Therefore many years ago we moved away from Foley catheters because of the high glans dehiscence rate.

Most surgeons administer acetaminophen for postoperative pain control, whereas close to half of surveyed urologists include nonsteroidal anti-inflammatory drugs (NSAIDs) (Morrison et al., 2014). **Ibuprofen appears safe even in the immediate postoperative period despite concerns for bleeding.** A study by Schroder et al. (2018) suggests that standing doses of acetaminophen and ibuprofen can maximize pain control and minimize the need for supplemental narcotic administration. Around-the-clock dosing can be tapered within 48 to 72 hours of the procedure, after which the surgical pain experienced decreases (Schroder et al., 2018; Wilson et al., 2017).

Complications of Hypospadias Repair

When Duckett discussed hypospadiology, he highlighted the blend of art and science that produces a successful repair, describing it as a humbling process, a time- and energy-consuming task that confounds the surgeon. Pediatric urologists with experience understand this (Duckett, 1995). **Despite continued technical modifications and advances, successful penile reconstruction for boys with hypospadias remains a great challenge. A combination of factors threatens to compromise even the most meticulous repair. The structures are delicate. The healing process is dependent upon fragile neovascularization. Postoperative edema, the risk of infection, and the**

inherent variability in the healing process add to the risk. Anyone who prepares to treat boys with hypospadias must have a broad and deep understanding of the potential risks and be committed to careful preoperative study, meticulous surgical management, and zealous postoperative care.

Today there is a lack of standardized definitions for hypospadias complications, leading to variability in reporting and inconsistency in the literature. Through efforts at multiple centers across the world this is changing, and some standard definitions are represented in Table 45.1.

TABLE 45.1

Complications and Definitions

URETHROPLASTY COMPLICATIONS	SKIN COMPLICATIONS
Fistula	Skin surplus or deficiency with penile tethering
Glans dehiscence	Penile torsion >30 degrees
Meatal stenosis	Preputial fistula
Urethral stricture	Preputial dehiscence
Urethral diverticulum	Postpubertal phimosis
Recurrent curvature >30 degrees	Lichen sclerosus
STANDARDIZED DEFINITIONS	
Urethroplasty Complications: Primary Outcome • Fistula: urethral leak anywhere below the meatus • Glans dehiscence: complete separation of the glans wings resulting in a coronal or more proximal meatus, or complete separation of glans wings with an intervening bridge of skin; objectively: glans fusion measurement <2 mm • Meatal stenosis: obstructive symptoms (straining, prolonged voiding, urinary tract infection, and/or retention) *and* meatal calibration <8 Fr before puberty or <12 Fr after puberty • Urethral stricture: obstructive voiding symptoms (stranguria, prolonged voiding, urinary tract infection, and/or retention) with visual near closure of the urethra on urethroscopy • Urethral diverticulum: visual segmental sacculation of the urethra during voiding • Recurrent curvature: residual ventral, dorsal, or lateral curvature >30 degrees demonstrated on erection (spontaneous or artificial)	
Skin Complications: Secondary Outcome • Skin surplus: Excess skin ≥2 cm in a circumcised patient when the suprapubic fat pad is retracted	

- Penile torsion: angle between the normal and true vertical glanular plane >30 degrees from midline (specify clockwise or counterclockwise)
- Nonretractable reconstructed preputium: cannot visualize meatus (in the absence of lichen sclerosus), acceptable before puberty, abnormal after puberty
- Preputial dehiscence after preputial reconstruction: defect in the preputial skin recreating an incomplete prepuce
- Preputial fistula after preputial reconstruction: fistula-like defect in the preputial skin that has no contact with the urethral lumen
- Lichen sclerosus: white cicatrix, preferably with pathology diagnosis

Courtesy Warren Snodgrass, MD.

Urethrocutaneous Fistula

Urethrocutaneous fistula is the most common reported surgical complication after hypospadias repair, with an incidence just under 10% in short-term follow-up (el-Kassaby et al., 2008; Grosos et al., 2014; Pfistermuller et al., 2015; Snodgrass and Bush, 2011; Fig. 45.30). A fistula can develop anywhere along the length of the urethroplasty, although most often at the site of the original urethral meatus or at the coronal margin. They range from a pinpoint opening with a small urine drip to a large defect through which all urine flows. The development of a fistula is multifactorial, with ischemia, edema, infection, and/or hematoma contributing to improper healing of the neourethra. Distal urethral obstruction from meatal stenosis or urethral stricture results in high urethral pressures and turbulent flow during voiding. This places additional stress on the suture line and can decrease the perfusion of the tissues during wound healing. Technical factors such as overlapping of suture lines, inadequate inversion of the epithelium, or use of poorly absorbable suture material may also contribute (Eardley and Whitaker, 1992). All of these factors become even more evident as the severity of the hypospadias worsens, further increasing the complication rate (Arlen et al., 2015; Bush et al., 2015; Spinoit et al., 2015).

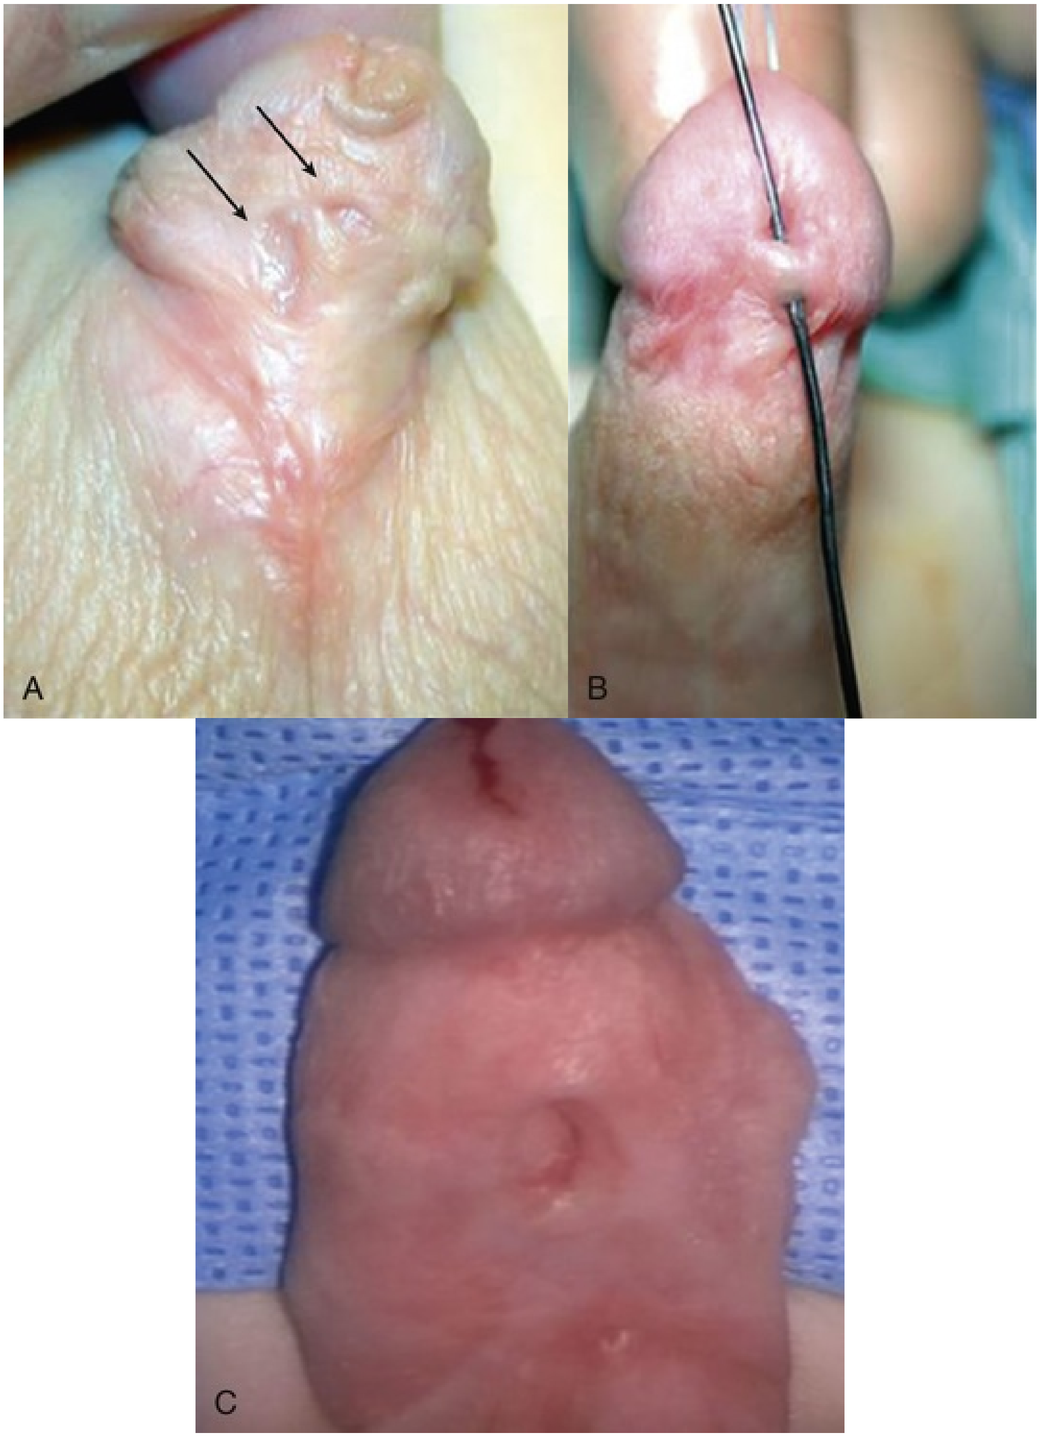

FIG. 45.30 Examples of various urethrocutaneous fistulas, each depicted with *black arrows.* (A) Two fistulas are noted. (B) A lacrimal duct probe lies within the fistulous tract. (C) A midshaft fistula is present.

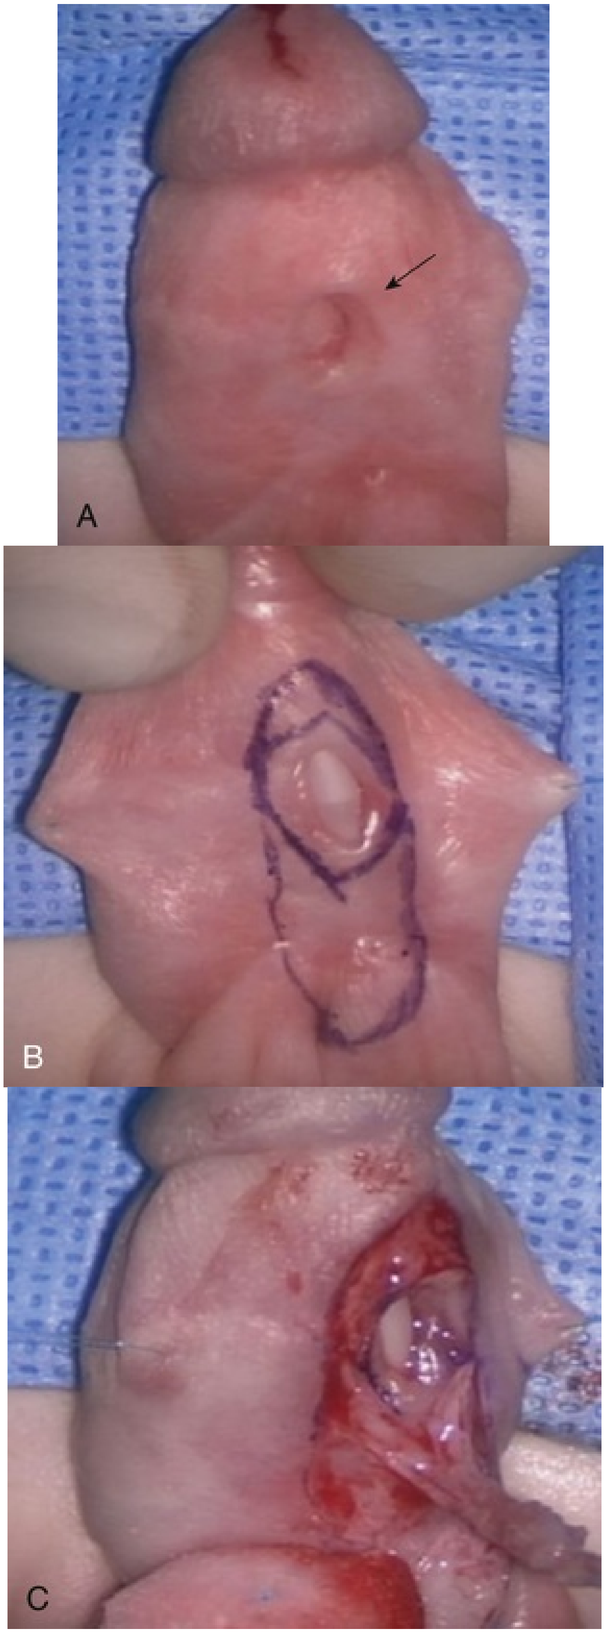
Management of urethral fistulae depends on the number, size, location, and the presence of additional complications. Multiple urine streams may be noticed by the parent if the child voids during a diaper change, and most are noticed in the first 2 years after surgical repair (Grosos et al., 2014; Spinoit et al., 2013; Wood et al., 2008). Fistula diagnosis may be delayed until toilet training, when voiding is more likely to be observed.

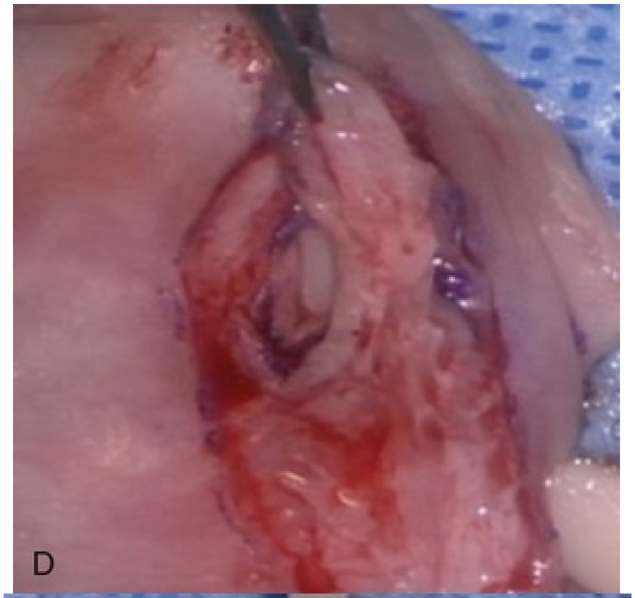
Small fistulas noted in the immediate postoperative period without concomitant inflammation or meatal stenosis rarely close on their own (Chandrasekharam, 2016). The majority of urethrocutaneous fistulas require surgical repair, which is delayed until at least 6 to 12 months after the initial hypospadias repair to allow wound healing and tissue softening.

If a fistula is suspected, a careful evaluation in the operating room may include calibration with a bougie à boule to assess the patency of the urethra and to identify irregularity in the urethral caliber, which commonly accompanies the development of a fistula. If calibration suggests irregularity in the urethra, urethroscopy should be performed. As a further test, a urethral catheter or a venocath may be inserted and saline injected into the urethra with the proximal and distal lumen compressed, performing a “stress test” to identify concealed fistula tracts.

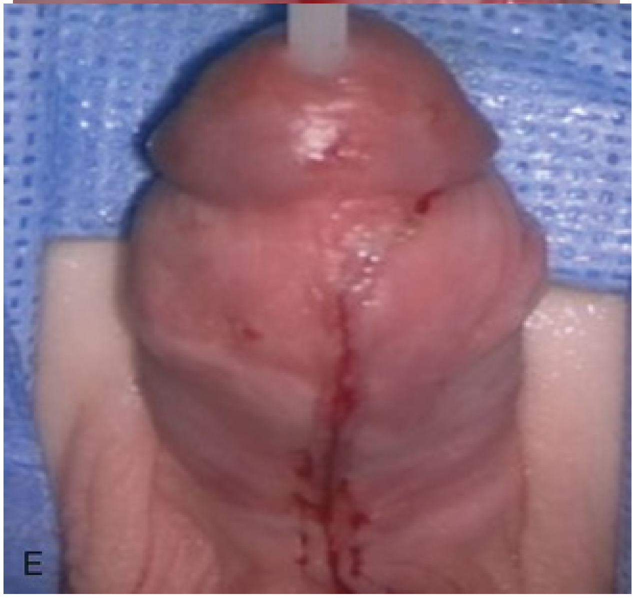
Small-caliber fistulas on the penile shaft proximal to the coronal margin can be closed primarily, taking care to excise the epithelialized tract to the urethra (Santangelo et al., 2003; Fig. 45.31; ▶Video 45.13). The urothelial edges can be closed in a subepithelial fashion. Multiple overlapping layers are placed to prevent recurrence. Larger fistulas, or those that are present in areas where the tissues have thinned, require coverage with a trap-door or island flap of penile shaft skin. Good results depend on a second layer or a vascularized flap coverage, secured in an offset fashion (Cimador et al., 2004; Elbakry et al., 1998; Santangelo et al., 2003).



A
B
C



D



E

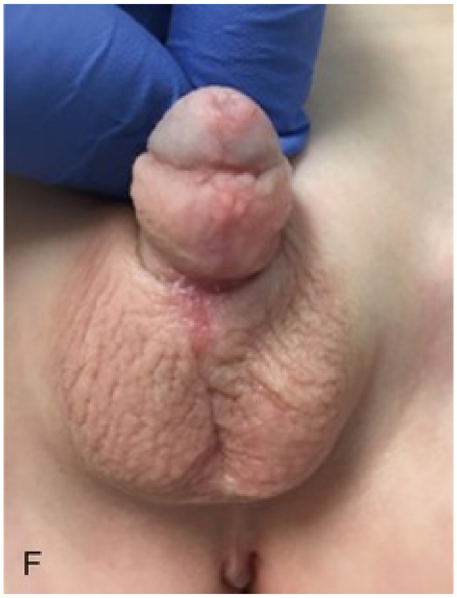


FIG. 45.31 Repair of urethrocutaneous fistula after a prior two-stage proximal hypospadias repair. (A) Distal shaft urethrocutaneous fistula *(arrow)* with an intact glans and patent meatus. The distance from the glans is a key component in the decision making for fistula management. (B) Incision is marked, first around the fistula tract and then secondarily to raise flaps for barrier coverage. (C) Incisions are made and the fistulous tract is isolated. The surrounding skin is undermined to sufficiently mobilize tissue for skin closure as well as barrier layers. (D) Fistula tract is closed in a primary fashion and dartos layers are approximated over the repair. (E) Skin is closed. (F) Six-month postoperative picture with no evidence of recurrence.

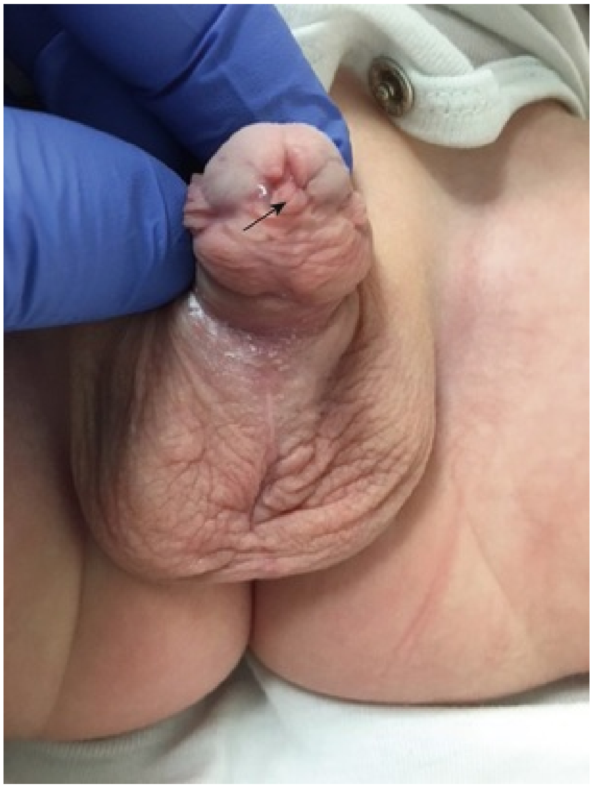
Fistulas at the coronal margin are more challenging. Although it is tempting to perform excision and primary closure, a fistula at this site can suggest a distal narrowing or poor local tissue that requires revision of the urethroplasty to achieve a satisfactory repair (●Video 45.14).

Despite a well-performed repair, fistulas recur about 20% of the time (Snyder et al., 2005a; Sunay et al., 2007). This recurrence rate may be lessened with interposition of multiple well-vascularized nonepithelialized layers between the urethral closure and the skin. Redundant dartos tissue, if present, or a scrotal-based tunica vaginalis flap may also be used (Fahmy et al., 2016; Routh et al., 2008; Shankar et al., 2002). Scrotal dartos tissue has been used in a similar fashion (Churchill et al., 1996). A de-epithelialized flap may also be used with success (Santangelo et al., 2003). In cases in which tissue is scarce, supplemental coverage can be taken from adjacent de-epithelialized shaft skin with a subsequent Cecil modification, reviewed in more detail later in the chapter (Cecil, 1946; Ehle et al., 2001; Weiss et al., 2018). There is no need to divert the urine for simple repairs, but for more complex redo repairs, we routinely divert the urine for 7 to 14 days (Holland et al., 2008; Redman, 1993; Santangelo et al., 2003).

Glans Dehiscence

Glans dehiscence is due to a combination of factors, including undue catheter tension on the repair as noted earlier, poor technique, tension on the glans closure, and vascular compromise (Fig. 45.32). If this occurs, the meatus typically regresses back to the corona or subcoronal location. **Reoperation may or may not be necessary and should be driven by the presence or absence of voiding symptoms. If repair is indicated, an interposition inlay graft may be required as an intermediary step for a staged repair to avoid tension on the glans closure** (▶Video 45.15).



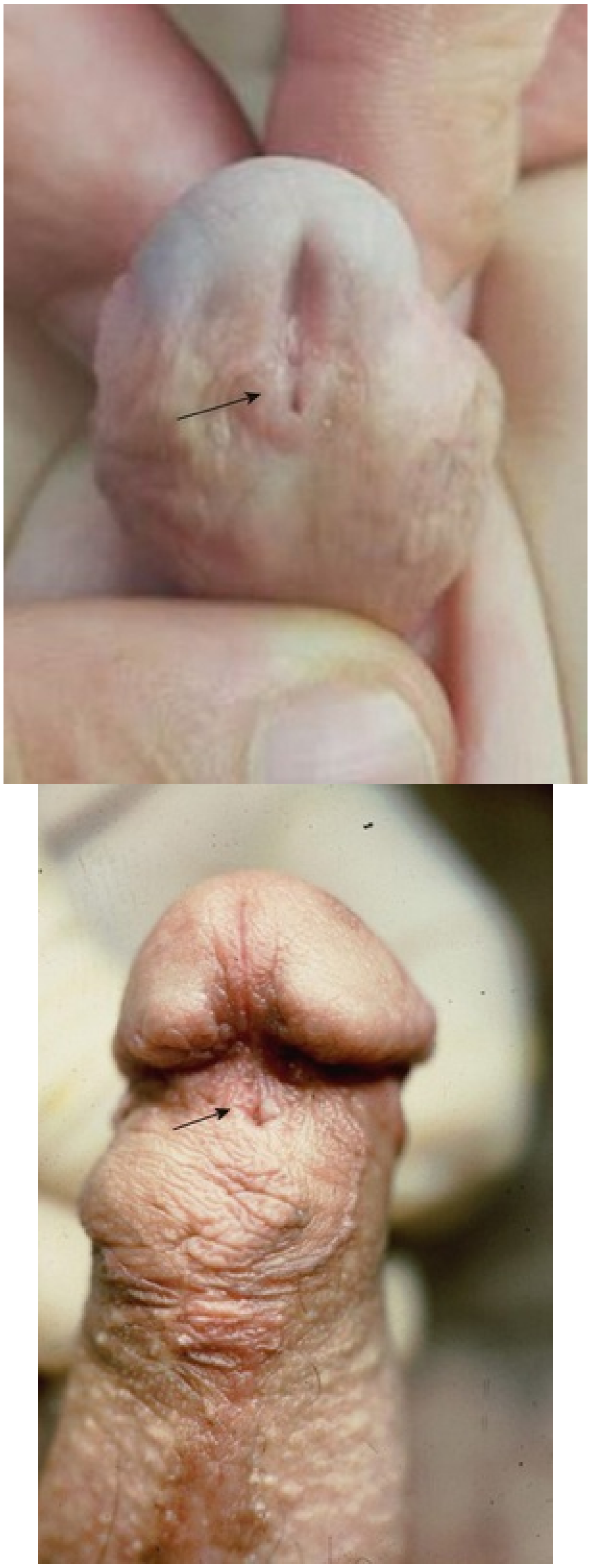


FIG. 45.32 Examples of glans dehiscence. All have a meatus below the corona *(arrows)* and lack of fusion of the glans wings in the midline.

Meatal Stenosis

Definitions for meatal stenosis vary considerably across studies (Wilkinson et al., 2012). Risk of narrowing increases if the urethra closure extends too distally or if the glans is closed with too much tension. Prolonging the time of postoperative stenting may decrease the risk of stenosis, although there are fewer data to substantiate this assumption (Daher et al., 2015). In the postoperative period the meatus should calibrate to a size no less than 8 Fr, and this should increase with age. **A narrowed meatus with symptoms of stranguria, deflected stream, poor uroflow, or urinary retention would suggest a clinically relevant stenosis that warrants repair**. Occasionally a stenotic meatus can be managed conservatively with meatal dilation with a sound and/or topical betamethasone cream (Radojicic and Perovic, 2006). Repeated dilation after hypospadias repair is not necessary as a routine practice to decrease rates of stenosis (Lorenzo and Snodgrass, 2002). It is not part of our practice but has been reportedly successful when the meatus appears narrow in the early postoperative period, and it may be diagnostic of subclinical stenosis. When the stenosis is refractory to dilation, a dorsal midline meatotomy can achieve patency in rare cases (Brannen, 1976). Otherwise a redo urethroplasty is indicated.

Meatal retrusion occurs when excessive tension on the distal urethra or the glans dehiscence has occurred (Duckett and Snyder, 1992). Meatal retrusion in part is due to improper surgical planning, resulting in an immobile or poorly vascularized urethra that retracts in the initial postoperative period because of undue tension. The consequences of this complication may be cosmetic or functional. If deflection of the stream precludes normal voiding while standing, revision of the meatus should be considered (Marte et al., 2001).

Urethral Stricture

Urethral narrowing that extends more proximally than the meatus is also a frequently reported complication of hypospadias repair, with rates varying depending on urethroplasty technique and length of urethroplasty (Duel et al., 1998; Husmann and Rathbun, 2006). These strictures tend to form at the junction of the native and neourethra, along the path of the neourethra, or within the glans. The clinical picture can vary, but complaints of a diminished urine stream force, stranguria, urinary retention, or urinary tract infection are most common.

Several factors increase the risk of postoperative stricture. Improper urethroplasty technique, tissue ischemia, trauma, or infection can result in narrowing of the lumen. When clinically apparent, it is best to characterize the stricture via cystoscopy to delineate the length, caliber, and location of the stricture.

Initial management depends upon the severity of the stricture. For short strictures causing minimal symptoms, urethral dilation or endoscopic incision can be attempted. In most cases, however, this will not provide a long-term solution. Direct visual internal urethrotomy in adult strictures has low success rates and risks worsening the stricture by generating more inflammation and scar (Santucci and Eisenberg, 2010; Tang et al., 2008). Success rates for small strictures (less than 1 cm), even when done in conjunction with intermittent catheterization, are poor: only 20% of boys exhibit a normal flow rate 2 years postincision (Husmann and Rathbun, 2006). The outcome may be better for short anastomotic strictures when endoscopic treatment is initiated 3 months after operation, although in our experience conservative management is rarely successful in these patients (Duel et al., 1998).

Strictures not responding to conservative management or those with extensive disease at diagnosis require revision urethroplasty (Gargollo et al., 2011). The surgeon must be prepared to harvest a local skin flap or buccal mucosa because there will likely be significant tissue loss at the site of stricture. This often results in a multistage repair, as discussed further in the reoperative hypospadias section.

If hair-bearing skin is used for the hypospadias repair, the patient may notice hair extending from the meatus. This complication usually occurs after multiple-stage procedures or complex reoperations in which there is a shortage of non–hair-bearing skin. Hair in the urethral lumen, if combined with urethral narrowing, acts as a nidus for stone formation or recurrent UTIs. Laser ablation may result in success in some cases (Cohen et al., 2007; Neal et al., 1999). Stone debris can be endoscopically removed in the majority of cases. In most cases in which stones, hair, and UTI coexist, the surgeon must resect the affected portion of the urethra and replace it with new tissue, such as a buccal graft, or in the unusual case in which redundant local skin is present, a local graft or flap.

Recurrent UTIs should prompt evaluation for urethral diverticulum or stricture. Occasionally, a voiding cystourethrogram or cystoscopy demonstrates an enlarged prostatic utricle, which can promote urinary stasis resulting in bacterial colonization. If no other source of infection is obvious, consideration should be given to either excision or fulguration of the utricle (Ciftci et al.,

1999).

Urethral Diverticulum

Symptoms of urethral diverticulum include weak urinary stream, postvoid dribbling, UTI, or, less commonly, hematuria. The boy or his parents may notice ballooning of the penile shaft during voiding or report the need to “milk” residual urine from the penile urethra to avoid soiling of the underwear. Diverticula occur more commonly in boys undergoing preputial flap repairs, two-stage repairs, and proximal repairs (Snyder et al., 2005b). This is in part anatomic, because of the lack of spongiosal tissue in the neourethra, which acts to reinforce the normal urethra during voiding. As mentioned earlier, the extra support of the glanular neourethra after glans closure can increase voiding pressure in the penile urethra, leading to diverticulum formation (Radojicic et al., 2004).

A small, localized saccular diverticulum can be excised and reduced, returning the urethral lumen to a uniform caliber. The more commonly encountered extensive diverticula are repaired by excising redundant diverticular tissue, urethral closure, and multilayered reinforcement before skin closure (Zaontz et al., 1989; Fig. 45.33; ▶Video 45.16). The redundant tissue of the diverticulum is well vascularized in some instances, making it an ideal candidate for repair of associated fistulas and distal strictures, if present (Radojicic et al., 2004). Various flap techniques have been employed to reconfigure redundant diverticular tissue for this purpose (Winslow et al., 1985). Urethral plication in an extraurethral fashion is an alternative technique that does not violate the urethral plane (Heaton et al., 1994).

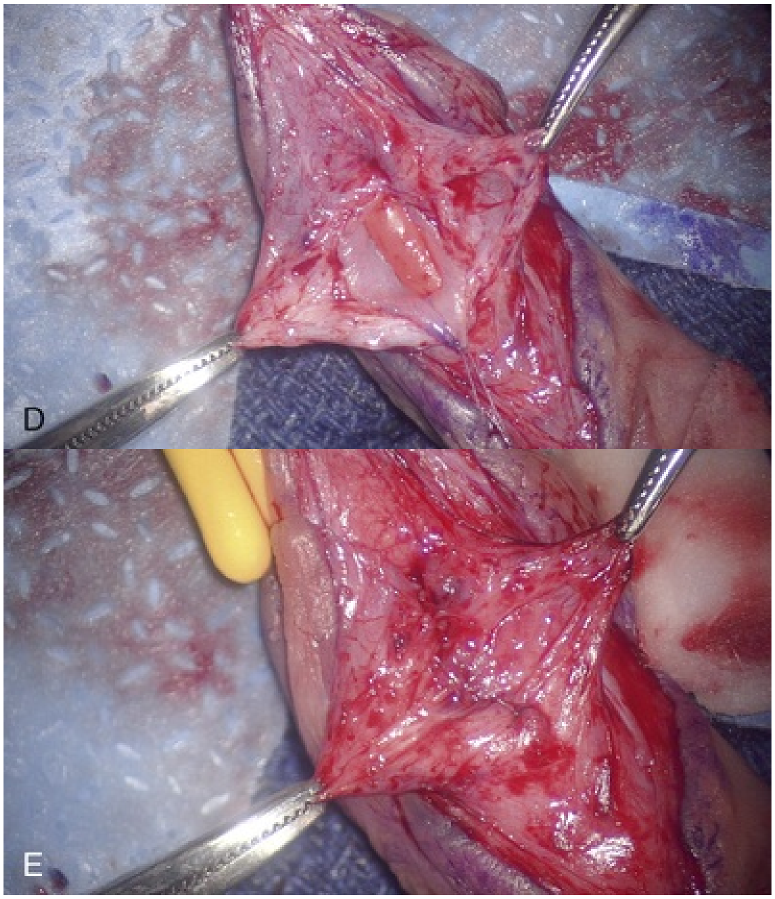

FIG. 45.33 (A) Urethral diverticulum on exam with a sacular dilation of the distal urethra *(arrow).* (B) Diverticulum is evident after ventral penile incision and partial degloving. (C) Diverticulum cavity is open and stay sutures are in place. Markings indicate the edges of urethral closure. (D) Excess epithelial tissue is excised, leaving redundant dartos tissue for extra layer closure over the urethra. (E) Urethral closure before barrier layer approximation.

Balanitis Xerotica Obliterans

Balanitis xerotica obliterans (BXO), or lichen sclerosus, is a chronic inflammatory dermatosis that can occcur in uncircumcised boys with phimosis, meatal stenosis, or progressive urethral narrowing after hypospadias repair (Fig. 45.34). Its management can prove difficult. If limited to the urethral meatus, the initial therapy is a course of topical steroids (betamethasone or clobetasol) or systemic tacrolimus (Kiss et al., 2001; Snodgrass et al., 2017). **In most cases, conservative therapy is unsuccessful and the surgeon must resect involved tissue and replace it with inner prepuce or buccal mucosa, in multistaged operations to fully reconstruct the penis** (Bracka, 2011; Dubey et al., 2005)**.**

Tissue should be sent to pathology to confirm diagnosis. These patients must be monitored closely for recurrence of BXO. Recurrence rates as high as 40% have been reported with median follow-up of 26 months (and as long as 105 months) from surgery (Snodgrass et al., 2017). **It is now recognized that BXO can and does invade buccal mucosa, further complicating treatment** (Levine et al., 2007; Snodgrass et al., 2017).

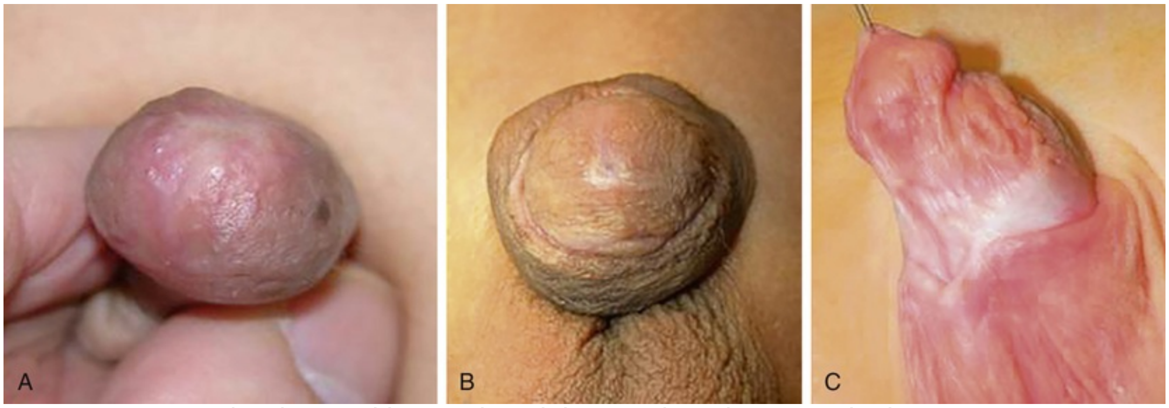

FIG. 45.34 (A,B) Balanitis xerotica obliterans (BXO) present in the meatus as evidence by the pale, white appearance to the tissue. Note the appearance on the penile shaft in C.

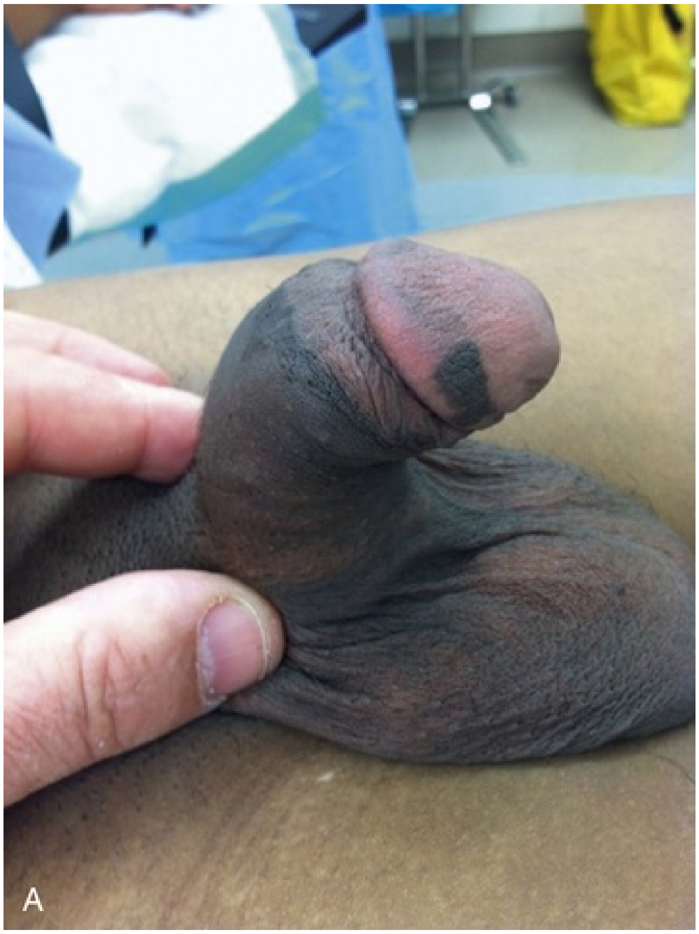
Recurrent Penile Curvature

Persistent penile curvature is an unfortunate complication of hypospadias repair that has severe consequences on urinary and sexual function. Residual curvature may worsen as boys advance through puberty, when penile growth surges with potentially differential growth of the dorsal and ventral portion of the corporal bodies (Barbagli et al., 2006). Persistent or recurrent curvature occurs when curvature is underestimated or is repaired incompletely (Braga et al., 2008). **If significant concern is present and intervention is indicated, the penis must be fully degloved and artificial erection performed.** Curvature may be present at the base of the penis, which can be obscured by the presence of a tourniquet. To properly assess this, artificial erection is performed with compression of the corporal bodies against the pubis. **Alternatively, prior preservation of a tethering urethral plate or ventral skin contraction can tether the penis ventrally.**

When curvature recurs, parents should be counseled that several procedures may be required (Fig. 45.35). The first stage assesses the cause of curvature, with particular attention to corporal disproportion if a dorsal plication was performed previously (Snodgrass, 2008). If a graft is used for corporoplasty, a healthy dartos layer should cover this area to act as a recipient for a buccal mucosa graft at the next stage of reconstruction. In many cases, a buccal graft to the ventral penile shaft is required for full penile reconstruction, unless a sufficient amount of skin is present to provide tension-free coverage. If shaft skin is deficient, we perform a Cecil modification during the third stage, which provides supple tissue for skin closure at the fourth stage (as outlined later) (Ehle et al., 2001).



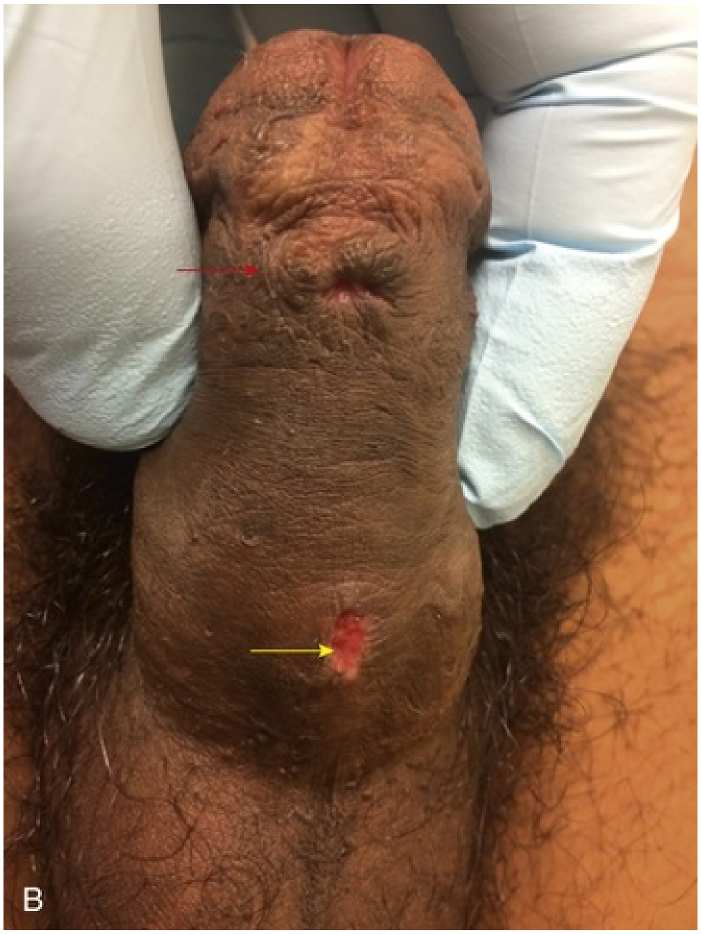


FIG. 45.35 A 14-year-old boy with a history of proximal hypospadias repair. He had undergone a single-stage hypospadias repair as an infant, including correction of his curvature with dorsal plication. He presented with significant ventral penile curvature, seen in (A). (B) Location of the urethral meatus after correction of the penile curvature in the first stage operation *(yellow arrow)*. There is a large gap between the proximal end of the distal portion of the urethra *(red arrow)* and the distal end of the proximal urethra. This boy required two additional procedures, the first of which was a buccal inlay graft with subsequent closure at the final stage.

Skin Complications

Although often perceived as minor, several skin complications may occur after primary repair. If penile concealment and poor skin fixation are present, a buried penis with shortening may occur. This condition may be avoided at the original surgery with penile shaft degloving and well-placed anchoring sutures that superficially attach Buck fascia to the corresponding dermis of the abdominal wall/shaft skin juncture. Suture sinus tracts can occur from suture reaction of the skin, particularly if thin ventral shaft skin is present or if full-thickness sutures are placed. In addition, tightly closed sutures may lead to ischemia and foster suture tracts. Patients with proximal hypospadias and/or penoscrotal transposition, penoscrotal webbing, or poor definition of the penoscrotal junction can result in an abnormal clinical appearance after repair. A scrotoplasty may be used in these settings to prevent postoperative penile concealment.

Hypospadias Outcomes

We have elected to combine the reported outcomes for distal and proximal hypospadias in a single section. **As we have mentioned throughout this chapter, there are significant concerns about the quality of the literature in its current form. Although thousands of publications can be found with a simple PubMed search, most if not all are limited to some extent by their retrospective nature, small cohort sizes, variations in technique, poorly defined outcomes, lack of independent outcome assessment, and patient loss to follow-up. This is recognized across our specialty and efforts to improve publication standards and quality collaboration across institutions are being made** (Braga et al., 2016).

In the largest and most comprehensive outcome analysis, a meta-analysis by Pfistermuller et al. in 2014 included 49 studies with 4675 boys having undergone a TIP repair (Pfistermuller et al., 2015). **They identified an overall complication rate of 10.6%, with a reoperation rate of 4.5%, at a mean follow-up of 16.1 months. Of the complications assessed, fistulae (5.7%) were most common, followed by meatal stenosis (3.6%), and urethral strictures (1.3%). The authors highlighted the high degree of variability in assessment of outcomes, limiting their ability to compare studies.** Outcomes were improved with use of an additional layer of dartos coverage, but proximal and reoperative cases had a significantly higher complication rate (Pfistermuller et al., 2015). In a similar meta-analysis comparing 1872 TIP repairs with 1496 Mathieu repairs, the overall complication rate was similar, occurring in 129 (6.9%) and 88 (6.7%) of boys (Wilkinson et al., 2012). Urethrocutaneous fistulas occurred equally in both repairs, although meatal stenosis was much more common after the TIP repair. These authors also highlighted the difficulty in comparing studies, specifically the poor quality of the data, including surgical indications, lack of follow-up, and lack of clarity in defining outcomes.

Recurrent UTIs are uncommon after hypospadias repair, occurring in 43/2249 (1.91%) of boys in a large study from the group in Toronto in the postoperative period after urethral stent removal (Wehbi et al., 2014). In this population, diagnostic imaging identified several anomalies: distal urethral narrowing in 17/43 (40%), VUR in 14/43 (33%), urethral diverticulum in 5/43 (12%), and an enlarged utricle in 5/43 (12%). Comparing boys who underwent TIP versus OIF, the TIP group was more likely to have an elevated PVR, whereas the OIF group was more likely to develop a diverticulum and/or fistula. **Based on these findings, surgeons should perform anatomic imaging for any boy with recurrent UTIs after repair.**

Prat et al. (2012) shared their findings from a single-institution study of 707 boys with distal penile to glanular hypospadias operated on over a 31-year period. Patients were included only if they had more than 1 year of follow-up. A variety of techniques were used throughout the inclusion period, including MAGPI, TIP, Mathieu flap, onlay flap, and a tubularized flap. The overall complication rate was 24% and worsened with increasing severity of the hypospadias. In a similar study of 366 distal hypospadias repairs at a median follow-up of 23 months, the reoperation rate for TIP, MAGPI, or OIF repairs was 21.3% (Spinoit et al., 2013). The complication rate was significantly higher for patients who had longer duration of follow-up and for those with a more proximal meatus.

A single-institution study of 578 patients undergoing TD distal hypospadias repair reported a complication in 17.4% of patients (Grosos et al., 2014). The median follow-up was 25.6 months, with urethrocutaneous fistula and glans dehiscence occurring more commonly in the first year, whereas urethral stricture occurred more commonly as a late complication. Successful outcomes in distal hypospadias is high, ranging from 83% to 95% (Perlmutter et al., 2006; Pfistermuller et al., 2015; Rushton and Belman, 1998).

Unfortunately, the overall complication rate for proximal hypospadias is much higher, ranging from 23% to 68% when reviewing papers that report only on proximal hypospadias and more mild forms being excluded (Castagnetti et al., 2013; Gorduza et al., 2011; Long et al., 2017; McNamara et al., 2015; Pippi Salle et al., 2016; Stanasel et al., 2015; Snodgrass and Bush, 2017a). **As with distal hypospadias repair, urethrocutaneous fistula is the most common complication, occurring in 3% to 45% of boys** (Gong and Cheng, 2017)**. This is followed by glans dehiscence and meatal stenosis. Urethral diverticula occur more frequently in the setting of a Byars flap repair or onlay procedure versus a two-stage graft repair (STAG or Bracka repair).**

Regardless of technique, the rate of recurrent penile curvature for two-stage repair of proximal hypospadias is relatively low, ranging from 0 to 10% of patients (Gong and Cheng, 2017; Long et al., 2017; McNamara et al., 2015; Pippi Salle et al., 2016; Snodgrass and Bush, 2017a; Stanasel et al., 2015). Two-stage repair with corporoplasty was associated with increased penile length and improved cosmetic results (Castagnetti et al., 2013). Penile length is an important variable, particularly with proximal hypospadias, as a survey of adult patients after infant repair reveals concerns primarily for shortened penile length (Andersson et al., 2018; Moriya et al., 2016).

The two-stage graft repair (STAG) has an overall reported complication rate of less than 25% (Ferro et al., 2002; Castagnetti et al., 2013; Snodgrass and Bush, 2017a). **The most common complication encountered was glans dehiscence and/or urethrocutaneous fistula.** The rate of recurrent penile curvature is low. Additional layers of closure and increasing the local blood supply have been shown to decrease the complication rate (Telfer et al., 1998). A comparison of four approaches to proximal hypospadias repair, including TIP, preputial island onlay, island flap tube, and a two-stage Bracka repair, found that repair approach did not affect complication rates (Castagnetti et al., 2013). Concerns for a skin graft incorporation over a corporal graft can be circumvented with dorsal plication techniques combined with proximal urethral mobilization to correct the majority of curvature (Warwick et al., 1997). Otherwise, if severe curvature persists a corporal graft should be performed and this would increase the risk for skin graft loss.

Several reports have indicated a high complication rate associated with the Byars flap two-stage repair (Long et al., 2017; McNamara et al., 2015; Pippi Salle et al., 2016; Stanasel et al., 2015)**. Complication rates ranged from 30% to 70%, with urethrocutaneous fistula representing the most common complication noted, followed by glans dehiscence.** Urethral diverticulum is also a potential complication, thought to occur as a result from a combination of a lack of spongiosum and lack of fixation of the flap onto the ventral penile shaft at the time of the urethroplasty, as mentioned previously.

The group from Texas Children's Hospital shared their 11-year experience with 56 boys with median follow-up of 34 months (Stanasel et al., 2015). The surgeons used a two-stage repair with at least 6 months between stages. Their overall complication rate, defined as any additional procedures planned beyond the initial two-stage repair, was 68%. In a similar report, the Boston Children's Hospital team reported their results over 20 years for 134 boys undergoing a staged repair for proximal hypospadias. They reported a complication rate of 49% with a median follow-up of 46 months, including fistula, diverticulum, meatal stenosis, and glans dehiscence (McNamara et al., 2015). Pippi Salle et al. (2016) from Toronto compared their experience with 3 separate techniques on 140 boys with proximal hypospadias: a long TIP, dorsal inlay graft, and a staged repair for proximal hypospadias. With mean follow-up ranging from 30 to 48 months, the complication rate was highest for a long single-stage TIP (53%) and lowest for the staged repair (32%). Our experience with proximal hypospadias repair at CHOP is similar. Of 167 consecutive boys with proximal hypospadias operated on from 2006 to 2014, 86 underwent a single-stage repair and 81 a planned two-stage repair. Median follow-up was 29 and 31 months, respectively. The complication rate was higher for the single-stage repairs compared with staged repair (62% vs. 49%, $P = .11$) (Long et al., 2017). Although mostly represented by case series, the two-stage approach incorporating distal urethra closure and correction of curvature at the first stage has reportedly favorable outcomes (Cheng et al., 2003; Dewan et al., 2004).

Castagnetti et al. (2013) sent a questionnaire as well as the penile perception score to 93 patients who underwent proximal hypospadias repair. These patients on initial exam all had ventral penile curvature that was reconstructed with an onlay island flap, onlay island flap on albuginea (a technical modification in which the onlay flap is anchored in the midline to the albuginea of the corpora cavernosa), TIP, or two-stage repair. Their significant findings include the achievement of a longer penis in the staged repair, improved cosmetic outcomes (as per the PPS) for the two-stage repair, and that the complication rate (23%) and urinary complaints were similar across all four surgical approaches.

To our knowledge no direct comparison of these three approaches mentioned earlier has been performed that would determine the ideal approach to proximal hypospadias with severe ventral penile curvature. Regardless of the approach taken, long-term outcomes data are lacking and raise concerns that more complications will be reported as these patients are followed over time (Grosos et al., 2014; Spinoit et al., 2013).

Outcome Assessment

In some cases, complications after hypospadias repair are not obvious. A urethrocutaneous fistula with multiple streams is easy to identify. However, subtle changes heralding stricture formation may be hard to appreciate. Visualization or measurement of the urinary stream in the office or on a video captured by family can be indicative of stricture. Urethral calibration in the office is not an easy task. If a high degree of concern is present for a stricture or meatal stenosis, then exam under anesthesia is warranted**. Uroflow can be performed to further characterize a slowed urinary stream, although exact definitions of a poor flow after a hypospadias repair are not well defined**

and difficult to obtain in the pre–toilet-trained population. It can also be difficult to predict which child needs surgical attention because improved flow rates with aging have been reported (Andersson et al., 2015).

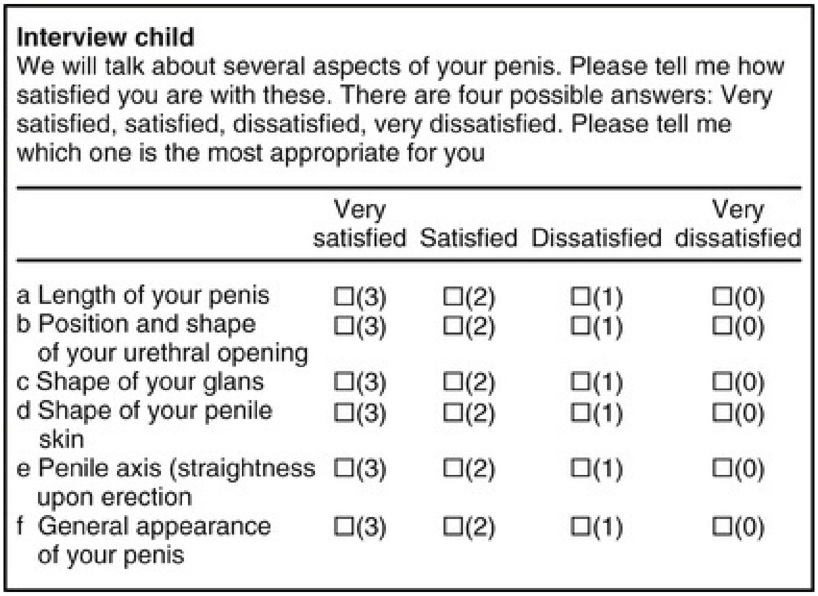
Some argue that the majority of complications are identified in the first year postsurgery (Snodgrass et al., 2014c). However, longer follow-up universally yields higher complication rates with only 50% of postoperative complications noted in the first postoperative year (Grosos et al., 2014; Spinoit et al., 2013; Wood et al., 2008). **Spinoit et al.** (2013) **examined 474 primary hypospadias repairs and identified only 54 of 114 (47%) of their complications within 1 year of surgery. By 36 months of follow-up, 88 of 114 (77%) had undergone repair of complications. In a similar study, Grosos et al.** (2014) **reviewed results following the Thiersch-Duplay technique and reported that only 57% of their complications were discovered during the first year of follow-up**. The type of complication varied according to the time to presentation, with fistulas occurring more commonly in the first year, whereas urethral stricture was more common beyond this time point. These findings suggest that although a majority of boys have complications identified early in the first 3 years of surgical follow-up, there is a large number that develop later complications.

Our practice has evolved to include a minimum standard of follow-up of our surgical patients through puberty, particularly for our proximal hypospadias patients. All patients follow up after toilet training to allow an assessment of the urinary stream. Extension of follow-up through puberty allows further evaluation of the voiding velocity, curvature, and sexual function at the completion of penile development.

Patient-Reported Outcomes

Much of the discussion in the chapter has focused on surgical procedures and their outcomes as observed by the *surgeon*. Although surgeon assessment, for fistula and glans dehiscence for example, is important, without patient input, the process is incomplete. In spite of what surgeons may determine a successful repair, parental and patient perception of their outcomes may differ (Lorenzo et al., 2014; Mureau et al., 1996)**. Analyzing issues that contribute to parental decisional regret include the development of complications, parental hesitancy regarding the potential surgery, and the desire for circumcision while improved parental education and understanding of hypospadias repair decreased conflict about repair** (Lorenzo et al., 2012, 2014). Further refinement of the patient experience can help stem some of the parental and patient disappointment, which can occur even in the setting of a successful repair.

To capture PRO, several hypospadias specific scoring systems have been developed. The Hypospadias Objective Scoring Evaluation (HOSE), Pediatric Penile Perception Score (PPS), Genital perception Score (GPS), and the Hypospadias Objective Penile Evaluation (HOPE) score are scoring systems that have been generated and validated in children (Holland et al., 2001; Mureau et al., 1995; van der Toorn et al., 2013; Weber et al., 2008; Fig. 45.36 and Table 45.2). **Each instrument incorporates similar components to varying degrees, including the meatus, the presence of a fistula, the quality of the urinary stream, penile length, skin appearance, and general penile appearance. The HOPE score is unique in that a standard set of postsurgery pictures are obtained and scored by independent panels consisting of parents, patients and pediatric urologists, including reference pictures ranging from normal to severely abnormal, resulting in a high degree of interobserver reliability for surgical outcomes** (Fig. 45.37). A recent review by Sullivan et al. (2017) examines these scoring systems in depth, highlighting the lack of assessment of sexual function and psychosocial factors related to the repair. The authors also note a strong bias toward surgical outcomes, such as the location and appearance of the urethral meatus, which may prove to be less important for patient and parent satisfaction. Finally, they recognize that in spite of recognition of the need for PRO, universal incorporation into outcome analysis has been poor in the literature.



Interview child

We will talk about several aspects of your penis. Please tell me how satisfied you are with these. There are four possible answers: Very satisfied, satisfied, dissatisfied, very dissatisfied. Please tell me which one is the most appropriate for you

	Very satisfied	Satisfied	Dissatisfied	Very dissatisfied
a Length of your penis	☐(3)	☐(2)	☐(1)	☐(0)
b Position and shape of your urethral opening	☐(3)	☐(2)	☐(1)	☐(0)
c Shape of your glans	☐(3)	☐(2)	☐(1)	☐(0)
d Shape of your penile skin	☐(3)	☐(2)	☐(1)	☐(0)
e Penile axis (straightness upon erection	☐(3)	☐(2)	☐(1)	☐(0)
f General appearance of your penis	☐(3)	☐(2)	☐(1)	☐(0)

FIG. 45.36 Pediatric Penile Perception Score instrument is administered to the patient and parents for assessment after hypospadias repair. Considerations include cosmetic satisfaction with the length of the penis, meatus, glans, penile skin, and straightness of the penis. (From Weber DM, Schonbucher VB, Landolt MA, et al.: The Pediatric Penile Perception Score: an instrument for patient self-assessment and surgeon evaluation after hypospadias repair. *J Urol* 180(3):1080–1084, 2008.)

TABLE 45.2

Hypospadias Objective Penile Evaluation (HOPE) Score

1. **Position of meatus**: Assess the position of the meatus.
   See HOPE score reference pictures (see Fig. 45.37).
   ☐ Position 1 (10 points)
   ☐ Position 2 (8 points)
   ☐ Position 3 (5 points)
   ☐ Position 4 (3 points)
   ☐ Position 5 (1 point)
2. **Shape of meatus**: What is the shape of the meatus?
   See HOPE score reference pictures (see Fig. 45.37).
   ☐ Normal (10 points)
   ☐ Slightly abnormal (7 points)
   ☐ Moderately abnormal (4 points)
   ☐ Severely abnormal (1 point)
3. **Shape of glans**: What is the shape of the glans?
   See HOPE score reference pictures (see Fig. 45.37).
   ☐ Normal (10 points)

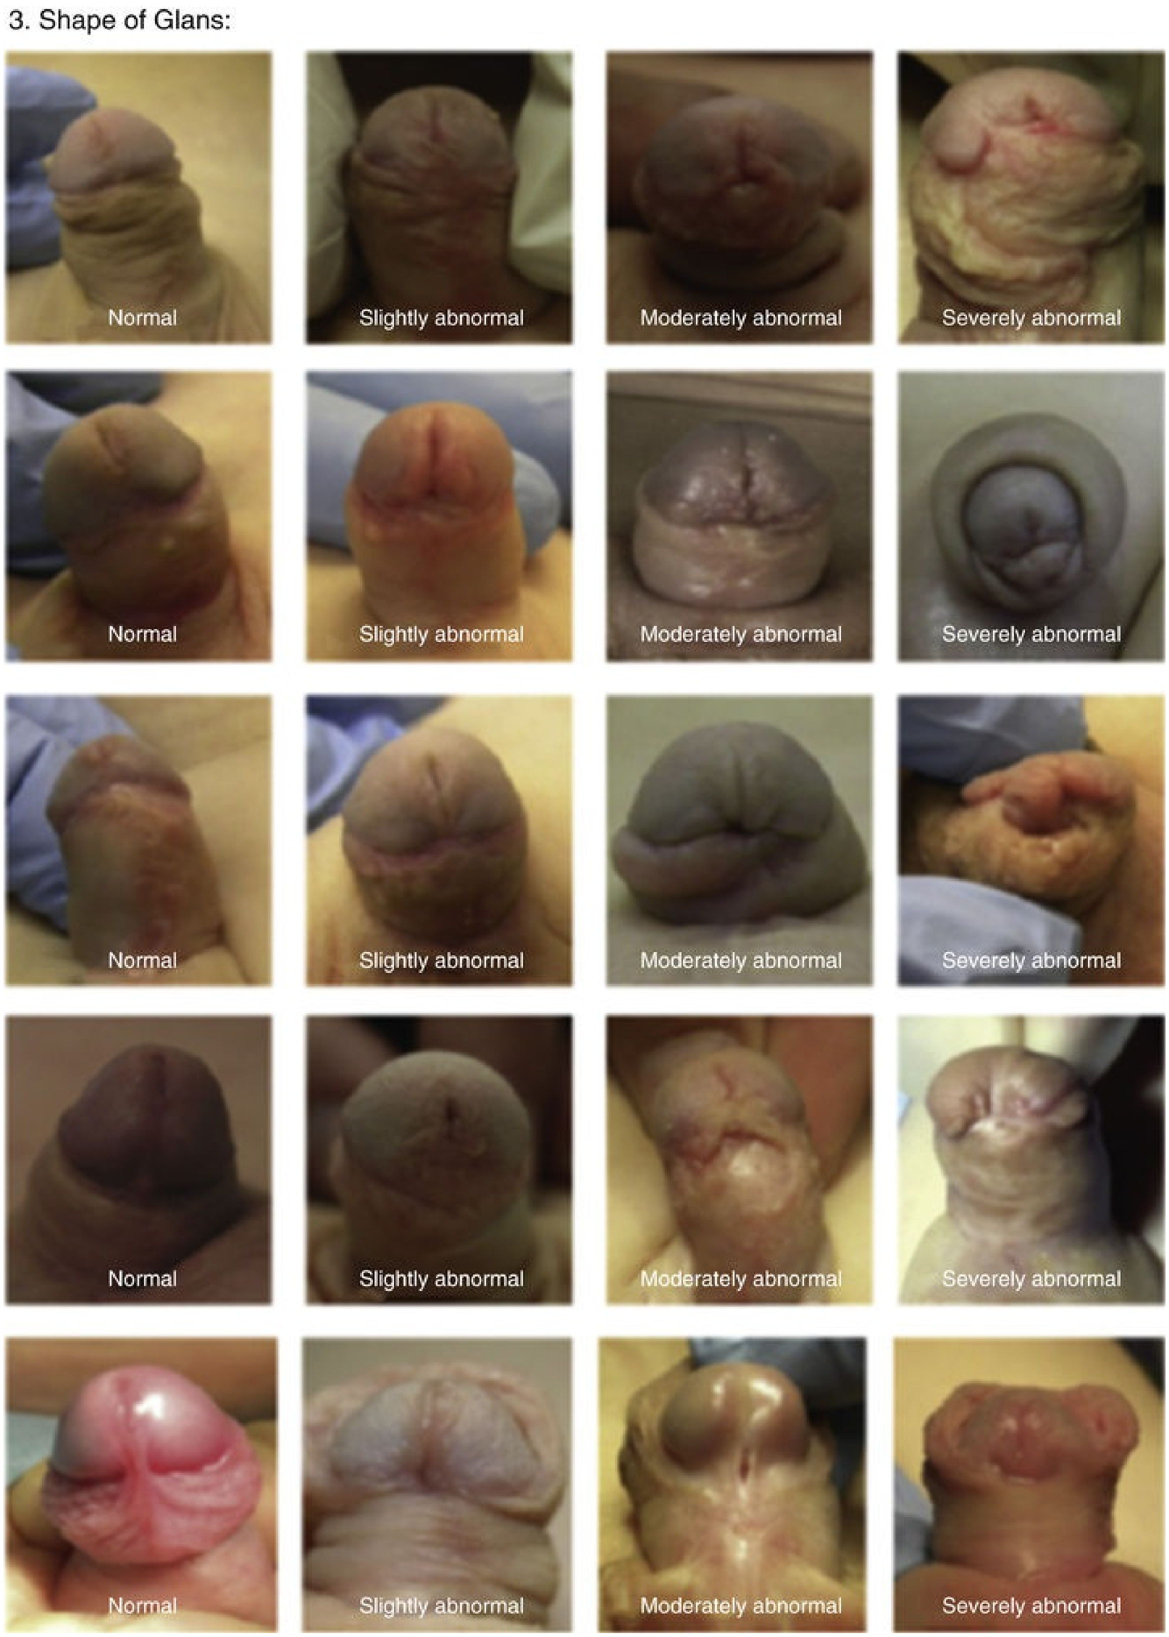
☐ Slightly abnormal (7 points)
☐ Moderately abnormal (4 points)
☐ Severely abnormal (1 point)

4. **Shape of skin**: What is the shape of the penile skin?
See HOPE score reference pictures (see Fig. 45.37).
☐ Normal (10 points)
☐ Slightly abnormal (7 points)
☐ Moderately abnormal (4 points)
☐ Severely abnormal (1 point)

5.1 **Torsion**: Is there a torsion of the penis?
See HOPE score reference pictures (see Fig. 45.37).
☐ 0–30 degrees (10 points)
☐ 30–50 degrees (7 points)
☐ 50–70 degrees (4 points)
☐ >70 degrees (1 point)

5.2 **Curvature in penile erection**: Is there a curvature of the penis in erection?
See HOPE score reference pictures (see Fig. 45.37).
☐ No erection observed (5.2 does not account for the HOPE score)
☐ 0–30 degrees (10 points)
☐ 30–50 degrees (7 points)
☐ 50–70 degrees (4 points)
☐ >70 degrees (1 point)

Hypospadias Objective Penile Evaluation (HOPE) score = mean number of points question 1–5.



3. Shape of Glans:

FIG. 45.37 Reference pictures administered in conjunction with the HOPE

scoring system (see Table 45.2) depicting various degrees of appearance ranging from normal to grossly abnormal. Anatomic assessment includes the position and shape of the meatus, the shape of the glans, the penile skin, and if any penile torsion and/or curvature is present. A numerical score for each of the 5 criteria ranges from 1 to 10, with a higher score given for a more normal appearance. (From van der Toorn F, de Jong TP, de Gier RP, et al.: Introducing the HOPE [Hypospadias Objective Penile Evaluation]-score: a validation study of an objective scoring system for evaluating cosmetic appearance in hypospadias patients. *J Pediatr Urol* 9[6 Pt B]:1006–1016, 2013.)

Although PRO regarding surgical and functional status is limited, they become more evident when examining sexual and psychosocial impacts. Although there has been a recent trend toward a focus on longer-term follow-up through puberty, the majority of hypospadias patients are still lost to follow-up. Assessment of 500 previously undiagnosed men with hypospadias revealed 65 (13%) with glanular to subcoronal hypospadias and 160 (32%) with anterior (proximal glanular) displacement of the meatus (Fichtner et al., 1995). The patients with previously undiagnosed hypospadias—all mild, distal variants with no penile curvature—had minimal sexual, fertility, or voiding concerns, with a number of men unaware that they even had hypospadias. Another study identified 56 men (mean 53 years of age) with hypospadias, 9 of whom had undergone previous repair but had a persistent defect (Dodds et al., 2008). Of this group, 20 patients who had spraying or angulation to their urinary stream did not elect to pursue repair. Eighteen of 56 men were unaware they had an anomaly, 53 were sexually active without concern, and 41 of 43 attempted and fathered a child. **Both of these studies suggest that when the defect is mild, the patients readily adapt and can compensate for the defect. On the contrary, men with more severe forms of hypospadias, such as a more proximal location and ventral curvature, do report worse sexual and functional outcomes** (Schlomer et al., 2014).

In boys who have undergone surgery, some studies have identified psychological concerns. Parental survey of boys aged 6 to 10 years of age identified behavior problems and poorer school performance, which was significant when compared with normal controls but also increased in boys with more severe defects (Sandberg et al., 1989). In a series of 34 men who underwent hypospadias correction at an average age of 5 years, in spite of normal sexual development by age the men having undergone surgery were delayed in initiating their first sexual encounter and were less sexually active in their current relationships (Berg et al., 1981). **A more contemporary series**

comparing 167 men with repaired hypospadias with 169 age-matched controls found that both groups had equal reported fertility, sexual satisfaction, and age of initiation of sexual activity (Ortqvist et al., 2017)**. Subgroup analysis did reveal a lower rate of sexual satisfaction, worse fertility, and decreased sensation in patients with proximal hypospadias compared with distal variants and controls.** An analysis of 55 men (ages 14 to 25) with a history of proximal hypospadias repair found that these individuals had concern about penile growth but little issue with the location of the urethral meatus (Andersson et al., 2018). Although the majority of these men did initiate sexual activity, a significant number of them were hesitant about sexual physical contact compared with both controls and those with distal hypospadias.

In general, men with a history of hypospadias repair do not manifest major psychological problems. However, they tend to be less satisfied with penile appearance, have more inhibitions in seeking sexual contacts as a result of embarrassment, and have a more negative genital appraisal. These men tend to manifest more anxiety, hostility, and lower self-esteem, some of which may be ameliorated by operating at an earlier age (Berg and Berg, 1983)**.** What remains unclear is if the dissatisfaction with the genitalia is due to the physical appearance, the surgical procedure, development of complications, or limitations in sexual relationships. A survey of individuals unaware of hypospadias was conducted to determine their ability to identify a difference in appearance between circumcised males and variable forms of hypospadias (Ruppen-Greeff et al., 2016). They concluded that men with distal hypospadias were perceived in a similar fashion to controls, whereas those with proximal hypospadias did trend toward a perceivable difference, although this effect was minor. Several studies corroborate these findings, suggesting that the sexual and psychological effects can occur but differ only minimally from controls for distal variants but worsen with increasing severity of the defect, although large-scale studies that incorporate validated PRO that encompass all elements of the patient experience will be able to assess these outcomes (Chertin et al., 2013; Jiao et al., 2011; Rynja et al., 2011).

Key Points

- Sixty percent of urethroplasty complications occur within 1 year after surgery. Complications such as urethral stricture or penile curvature can occur in a delayed fashion. Thus boys, particularly those with proximal hypospadias, should be monitored into puberty.

- Potential risk factors for complications after urethroplasty include a proximal meatus location, glans width less than 14 mm, a lack of a barrier flap over the neourethra, and having a prior hypospadias operation.
- Urethrocutaneous fistula is the most common complication after hypospadias repair. If there is supple tissue present, a primary closure can be attempted, but if thin glans tissue is present, redo urethroplasty and glans closure should be performed.
- Meatotomy or skin flap repair of meatal stenosis most often fails in the presence of BXO, whereas excision of all tissues affected by BXO with staged buccal grafting is considered most likely to succeed without recurrent stenosis. These patients have up to a 40% failure rate; therefore they must be closely monitored.
- Long-term follow-up of patients who have had a hypospadias repair indicates that they are more likely to have ejaculatory problems, are less satisfied with sexual function, and are more likely to be dissatisfied with the appearance of their penis than controls. Patient-reported outcomes are an underrepresented component of follow-up and must be a focus of future studies.

Hypospadias Reoperations

Although some complications such as a simple fistula or skin redundancy can be managed in a single intervention, others may require a multistaged repair with a well-thought-out surgical plan. The tissue available for reconstruction is variable. Its quality decreases with each trip to the operating room. Each successive procedure leaves the penis progressively scarred, changes the established blood supply, and decreases tissue options for reconstruction, all of which result in increasing complication rates with each unplanned operation (Snodgrass and Bush, 2017b; Snodgrass et al., 2009). This can result in a boy or man who has undergone repeated unsuccessful repairs, remaining with a significant defect with poor function, a so-called hypospadias cripple.

Devine reasoned that “once complications have occurred in hypospadias repairs, the surgeon has a tendency to attempt small operations, hoping to convert failure with a minimum of effort. This generally makes matters worse. In these cases, extensive resection of scarring, major shifts of tissues and meticulous reconstruction is necessary to transform a difficult problem into a therapeutic success" (Devine, 1973). Given the complexity of reoperative hypospadias repair and its high complication rate, this quote serves as an important guide to achieve the ultimate goal of a cosmetic and functional penis (Myers et al., 2012).

The assessment begins in the office. A careful history identifies any voiding, skin, and erectile concerns. The timing of previous repairs and operative reports, if available, provide very important information such as the previous use of tunica vaginalis flaps or grafts, the method used for urethroplasty and correction of penile curvature. In the operating room the surgeon should err on the side of obtaining more information as opposed to less, having a low threshold to perform a cystoscopy to fully delineate the anatomy. The skin and available tissues must be carefully assessed for possible usage, and an artificial erection should always be performed, regardless of the type of repair performed, because if this goes undiagnosed, it will have severe long-term consequences (Nozohoor Ekmark et al., 2015; Safwat et al., 2013; Snodgrass et al., 2009). Because of the variable nature of the non-virgin tissue, there is less certainty and uniformity in the blood supply to flaps and local skin. Thus every effort should be taken to add additional layers of coverage, such as tunica vaginalis, to increase the chance of tissue survival.

Depending upon the initial approach to repair, tubularization techniques can be used to redo urethroplasty or for fistula closure. Mathieu, Thiersch Duplay, and redo TIP have been described in instances when deemed appropriate by the surgeon with a reasonable degree of success (Bar-Yosef et al., 2005; Borer et al., 2001; Nozohoor Ekmark et al., 2015; Simmons et al., 1999). Alternatively, placement of an inlay graft after incision of the urethral plate can improve outcomes in reoperative hypospadias, although surgeons must use caution when using tissue that has already failed closure in the past and now has a more variable blood supply (Kolon and Gonzales, 2000; Snodgrass et al., 2009; White and Hanna, 2018).

Salvage hypospadias for a focal issue (fistula, diverticulum) in the absence of penile curvature can be performed using local or remote skin flaps, which can be used as an onlay flap or for multilayer vascular flaps (Nozohoor Ekmark et al., 2015; Patel et al., 2005; Snodgrass et al., 2009). **We typically take this approach when redundant penile shaft skin is present from the original repair as it provides a source of non–hair-bearing skin. Our experience with**

the split onlay skin (SOS) flap is such that even a small piece of skin on a vascularized pedicle can achieve its intended effect (Fig. 45.38)**. Once harvested, the flap can be used in its entirety as an onlay to augment the urethral plate for closure or split to provide additional skin coverage for shaft skin closure or de-epithelialized for additional supplemental layers over the urethroplasty.**

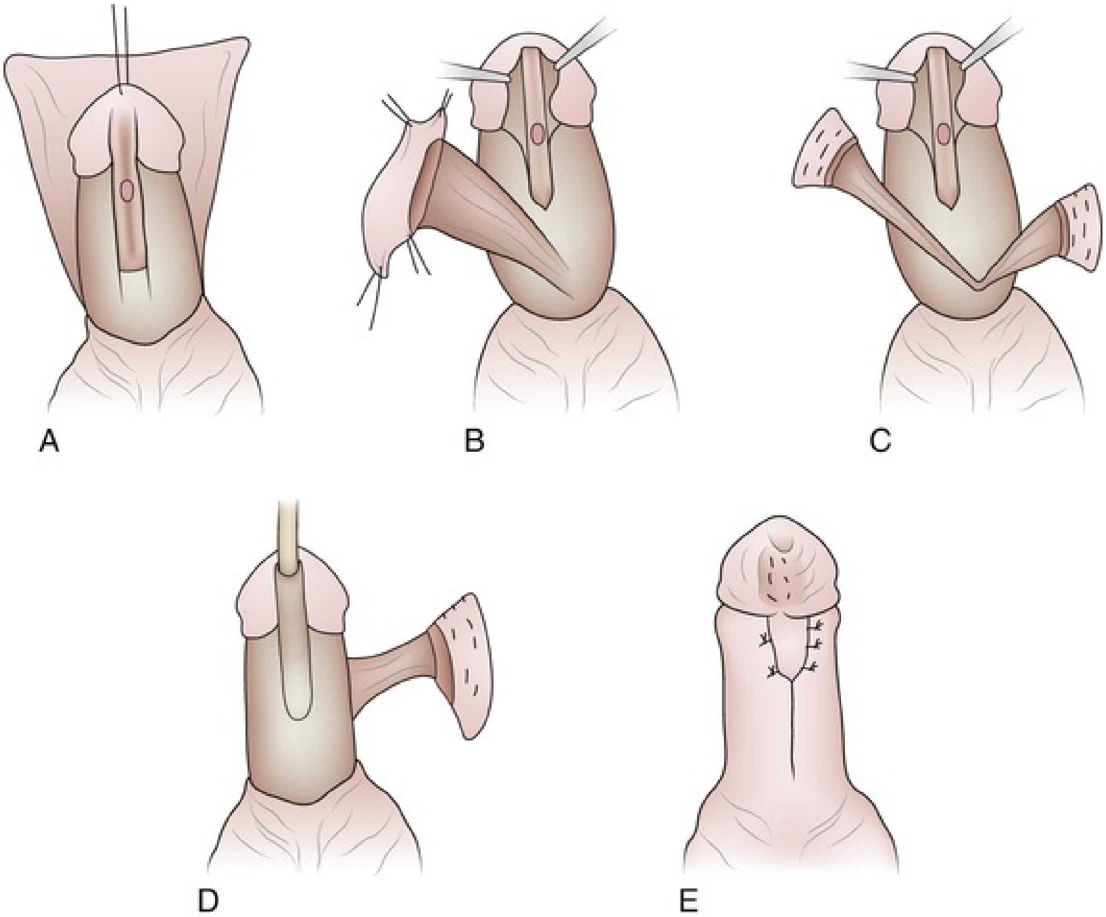

FIG. 45.38 Split onlay skin flap hypospadias repair technique. (A) A fistula is identified on the ventrum of the penis. (B) A skin flap approximately 1 cm in length is isolated and harvested, preserving its vascular pedicle. The flap can be harvested from any location with skin redundancy, either on the penile shaft or along the circumcision line. (C) Flap is divided into two segments, one to be used as an onlay for the urethral closure and the second either as a barrier layer or to facilitate skin closure. (D) Island onlay procedure is performed, closing the fistula. (E) Residual penile skin is approximated dorsally and the second half of the island flap is interposed to close the penile shaft skin. (From Patel RP, Shukla AR, Leone NT, et al: Split onlay skin flap for the salvage hypospadias repair. *J Urol* 173:1718–1720, 2005.)

Pharmacotherapy has been used to augment neovascularization or to improve local blood flow, potentially increasing flap and graft uptake. Topical nitroglycerin ointment can be applied after surgical reconstruction, typically for a period of 24 hours immediately after the repair (White and Hanna, 2018). **Nitroglycerin ointment exerts its effect on the arterial and venous systems, with a larger impact on the latter, and has been shown to increase blood flow to skin flaps as evidenced by fluorescein imaging, promoting improved survival** (Scheuer and Hanna, 1986)**. It has been used in complex hypospadias reconstruction and may provide benefit to ischemic tissues, although it has yet to be compared in a controlled, randomized fashion to determine its definitive impact** (Fam and Hanna, 2017; White and Hanna, 2018).

Hyperbaric oxygen (HO) has established clinical benefits in the setting of gas gangrene, radiation-induced necrosis, and diabetic foot ulcers, and has been proposed as a potential adjunct to promote neovascularization in the use of ischemic skin flaps and grafts (Friedman et al., 2006). HO promotes new vessel growth because of an exaggerated oxygen gradient and a reduction in tissue bacterial content (Park et al., 1992; Sander et al., 2009; Shaw et al., 2014). Its role in reoperative hypospadias is not yet established. Anecdotal reports are beginning to emerge about its potential benefits in graft take and improved vascularization (Kara et al., 2017; White and Hanna, 2018).

Subcutaneous tissue expansion allows the surgeon to augment autologous, non–hair-bearing skin for penile reconstruction in salvage procedures when scar tissue or lack of available skin threatens to compromise the reconstruction (Kajbafzadeh et al., 2007; Mir et al., 2011; Rochlin et al., 2014). A subcutaneous pocket is created under the penile shaft skin and a commercial, expandable device is inserted and inflated with saline. Additional saline is injected via a subinguinal injection port at 1- to 2-week intervals to gently dilate the tissue until sufficient tissue is developed. At the time of reconstruction, the device is removed and flaps of the expanded skin are rotated ventrally for penile shaft skin coverage or de-epithelialized to provide additional vascularized layers over the urethroplasty. One potential benefit proposed by authors is the preservation of androgen receptor–bearing shaft skin, which could prove a key factor in longitudinal growth during puberty (Celayir et al., 2007; Kajbafzadeh et al., 2007; Rochlin et al., 2014). In the largest study, Rochlin et al. (2014) operated on 42 patients with hypospadias. Although complications developed in 41%, including a 28% complication rate related specifically to the tissue expander, tissue expansion provided sufficient skin for reconstruction in 95% of these

patients.

Extragenital skin harvest is another option in the setting of salvage hypospadias repair. A graft is harvested and placed in a vascular bed on the ventrum of the penis, to augment or completely replace the urethral tissue. Several donor sites exist and have been used with variable success. **Single-stage repairs with full-thickness skin grafts have frequently failed secondary to graft shrinkage, scarring, and stricture formation, limiting their use** (Amukele et al., 2005; Webster et al., 1984).

Bladder mucosal grafts can be harvested and used to replace the urethral plate in cases where skin is damaged or scarce (Ehrlich et al., 1989; King, 1994; Memmelaar, 1947). Bladder mucosa contracts when exposed to air, which typically leads to narrowing of the neomeatus. Prolapse of the graft resulting in a cauliflower-type deformity is reported in up to 38% of patients. Meatal stenosis and stricture at the junction with the native urethra occurs frequently (Amukele et al., 2005; Hendren and Reda, 1986; Keating et al., 1990; Kinkead et al., 1994). **Although technical modifications may decrease the complication rate, extending its applicability, more recent success with buccal mucosa grafts has limited use of bladder mucosa** (Ehrlich et al., 1989).

Buccal mucosa is now the graft of choice in complex penile reconstruction (Brock, 1994; Bracka, 1995; Duckett et al., 1995). The tissue is ideally suited for urethral repair because it is well adapted to contact with fluid and air; it readily neovascularizes and is hairless; contraction is minimal; and harvest results in little damage at the donor site (Castagnetti et al., 2008). Contrary to other grafts, it retains its favorable histologic properties after placement (Mokhless et al., 2007; Soave et al., 2014). It also grows well in proportion to the phallus through puberty (Figueroa et al., 2014). Because of its elasticity and good tensile strength, buccal mucosa can be used to reconstruct the urethra in a single or multistage fashion, although a more conservative approach across two stages, allowing the graft to establish a blood supply before tubularization, is optimal (Faure et al., 2016; Ye et al., 2008). Long-term observation into puberty shows that if the graft is placed on a well-vascularized bed, the buccal graft is pliable and will not contract with age, an important aspect of management as we aim to avoid ventral penile curvature, which can result from a shortened, tethered urethra (Figueroa et al., 2014). Buccal mucosa can be harvested from the cheek, inner lip, or both. Reported local complications in men who have had buccal harvests include tightness of the mouth, transient numbness, motor deficits, scarring, and salivary duct obstruction (Wood et al., 2004).

Although single-stage buccal mucosa graft and tubularization can be performed and has been reported, the staged repair results in a higher success rate with improved graft incorporation (Hensle et al., 2002; White and Hanna, 2018). A dorsal inlay graft, in which the dorsal portion of the urethra is incised and the graft sutured in place, is a better alternative to either an onlay or a complete buccal tube, especially in the setting in redo repairs in which blood supply may be compromised (see Fig. 45.28).

Buccal mucosa taken from the upper or lower lip or tongue is thinner than that from the cheek and outcomes suggest that these grafts are better suited for urethral reconstruction, particularly in the glans. Local complications at the harvest site are no different for a lip or cheek location (Maarouf et al., 2013).

There are several important technical points when harvesting a buccal mucosa graft (Eppley et al., 1997). **The graft should be harvested 10% larger than the measured receiving bed to allow for graft contraction as it incorporates. Closure of the donor site may result in worsened postoperative pain with little objective benefit, because the sites heal by secondary intention** (Alwaal et al., 2015; Rourke et al., 2012)**. Although both are viable options for reconstruction, a labial graft appears to have fewer complications when compared with the inner cheek buccal mucosa, particularly an increased risk for glans dehiscence with cheek mucosa** (Lumen et al., 2016; Maarouf et al., 2013; Snodgrass et al., 2009). For longer defects in complex cases or in older children, buccal mucosa can be used because it allows for a larger graft size, although multiple sites can be combined to maximize tissue harvest (Morey and McAninch, 1996). **Strict attention to de-fatting and removing all nonmucosal tissue is important to maximize neovascularization.** The graft can be fenestrated with an 18- or 21-gauge needle and placed in saline until the recipient site is prepared. **Fenestration is thought to decrease hematoma formation, which can impede graft take. The recipient site is prepared by making an incision ventrally from the urethra through the glans to the site of the intended neomeatus** (Mokhless et al., 2007)**. Care should be taken to develop the recipient bed to preserve the underlying dartos, as this acts as the blood supply for graft uptake.** The graft is secured along its axis, taking care not to narrow the graft, which could lead to insufficient tissue for urethroplasty. Quilting stitches are typically placed to prevent hematoma formation. **The graft should be given at least 6 months to heal before proceeding with urethroplasty and skin closure, although it is our practice to wait 12 months before the next stage in reconstruction.** Regardless, periodic examination in the office must be performed to ensure proper graft take and to monitor for contraction. Topical steroids can be considered in the setting of some contraction in the postoperative period, waiting at least 1 month after placement. Outcomes after completion of the repair range from 30% to 75% success rate, with meatal stenosis the most common complication followed by stricture and breakdown of repair (Leslie et al., 2011; Metro et al., 2001).

The scrotum provides a rich vascular bed that can be taken advantage of in salvage hypospadias repairs. Originally described in 1946 by Cecil and modified by Culp (1951), it includes urethroplasty followed by midline scrotal incision and recession of the repair within the supple dartos bed. The penis is released at a second stage, originally reported by Cecil at 6 to 8 weeks, with the urethroplasty having parasitized the local blood supply, which aids the healing process of the urethra. **Although this repair fell out of favor with the emergence of single-stage repair and alternative techniques, it has re-emerged in the setting of difficult salvage procedures** (Fig. 45.39; Ehle et al., 2001; Fam and Hanna, 2017; Weiss et al., 2018). Concerns with this approach include the potential incorporation of hair-bearing scrotal skin on the penile shaft and the need for multiple procedures. **Weiss et al.** (2018) **have modified the approach by delaying penis release from the scrotum for a period of 9 to 12 months, increasing the transfer of secondary vascularized layers to the shaft, which in most cases eliminates the need for utilization of scrotal skin after the release of the scrotal flap**.

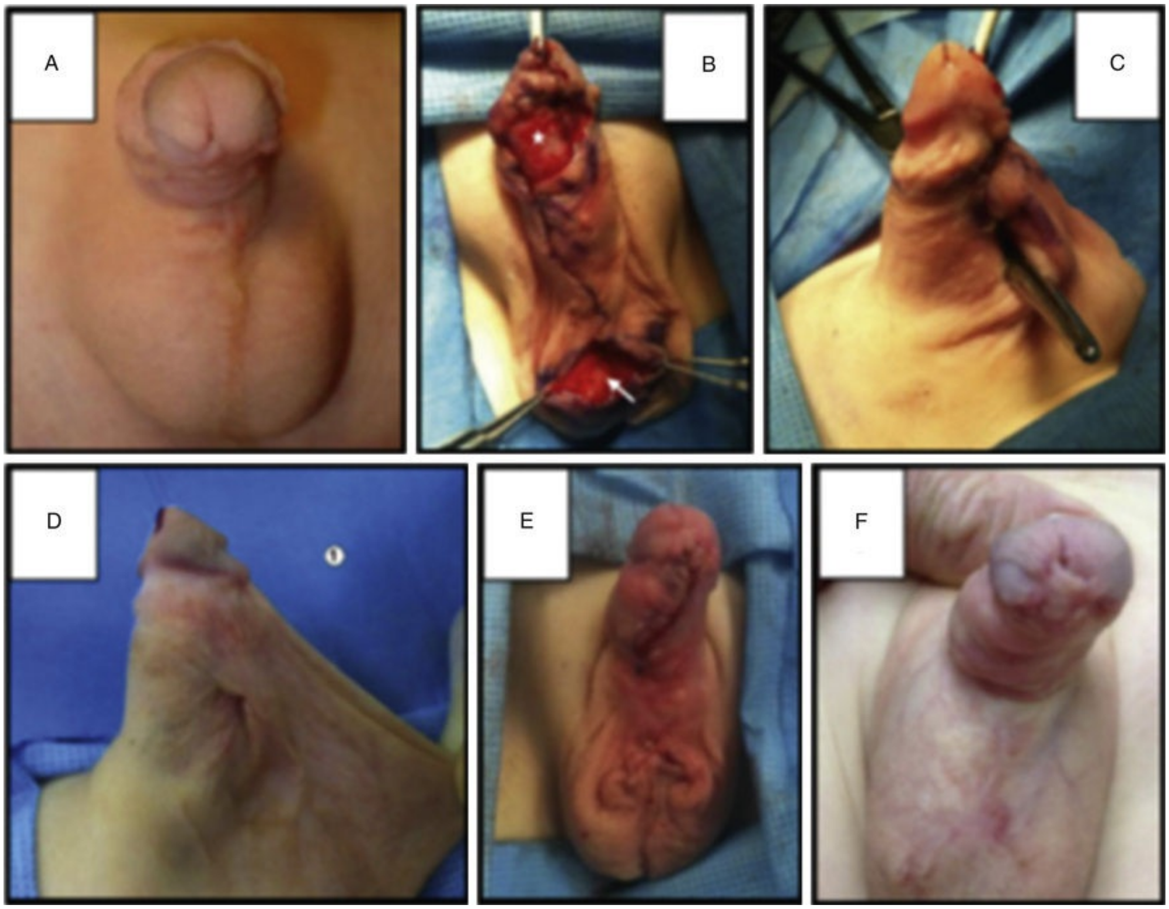

FIG. 45.39 Cecil-Culp repair for hypospadias fistula. (A) Initial appearance of a boy with a history of what was originally a penoscrotal hypospadias. He underwent a failed two-stage repair followed by buccal graft and re-ubularization. He came to us with two coronal fistulae and an irregular glans. (B) Intraoperative appearance after closure of fistulae and glans but a ventral skin defect (*) was present, precluding tension-free skin closure. A midline incision was made in the scrotum as the receiving site for the distal penile shaft anastomosis *(white arrow).* (C) Attachment of the penile shaft skin to the scrotal skin to cover the defect. (D) Approximately 1 year after Cecil-Culp placement, scar has softened and penile shaft skin has stretched. (E) Appearance after Cecil-Culp release, with midline anastomosis of penile shaft skin. (F) Three months postoperation from Cecil-Culp release. Glans is closed and there is no evidence of recurrent fistula. (From Weiss DA, Long CJ, Frazier JR, et al: Back to the future: Cecil-Culp technique for salvage penile reconstructive procedures. *J Pediatr Urol* 14[4]:328.e1–328.e7, 2018.)

Key Points

- For buccal mucosal reconstruction, lip tissue placement is preferable within the glans because it is thinner than cheek tissue and results in a lower complication rate.
- Buccal mucosa is now the graft of choice in complex penile reconstruction. The tissue is ideally suited for urethral repair because it is well adapted to contact with fluid and air, it readily neovascularizes and is hairless, contraction is minimal, and harvest results in little damage at the donor site. Contrary to other grafts, it retains its favorable histologic properties after placement.
- The Cecil modification provides an attractive alternative for skin vascularization in the setting of multiple prior repairs.

Future

As we have outlined in this chapter, there is room for improvement, the first step of which **will depend on continued honest reporting of our results. Reduction of complication rates will occur through standardization, allowing us to increase comparison across institutions with larger volume series and longer follow-up and incorporation of patient-reported outcomes.** To facilitate comparison within institutions (among surgeons) and across institutions, standardization of pre- intra-, and postoperative assessments according to exam, measurements, and outcome definitions must be agreed upon and accepted.

This should lead to establishment of multi-institutional collaborative efforts focused on identifying potential sources of complications that we are currently underpowered to assess with single-institution efforts (Joshi et al., 2018).

The fundamental aspect of this improvement process will be coaching and teamwork. **Coaching is used in athletics to maximize performance and perfection of technique, and we feel strongly that this approach can be applied to the more rare or difficult disease processes to improve our approach and outcomes, particularly for proximal hypospadias** (Borer et al., 2015; Gawande, 2011).

Much work remains to be completed in the advancement of surgical reconstruction of severe hypospadias (Long and Canning, 2016b)**. These efforts must focus on improving the relatively high complication rate, extending follow-up into adulthood, and using long-term analysis to guide patient and parental expectations of the repair.**

Clinical questions such as what is the ideal location of urethral meatus, what degree of penile curvature is cosmetically and functionally acceptable, and to what extent are boys willing to undergo painful and complicated procedures to achieve an ideal result still await an answer. This patient, with a history of proximal hypospadias repair left with a coronal meatus yet with good voiding parameters and an otherwise straight penis, has a satisfactory quality of life in spite of the meatus location (Fig. 45.40). Is that the case for all such patients? Other questions similarly await further study, such as how best to study the long-term psychological challenges of living with the birth defect and the ensuing penile reconstruction with the potential for multiple repairs. Perhaps another may be most important of all: How can we maximize our patient and parental education so that they are prepared for the road ahead?

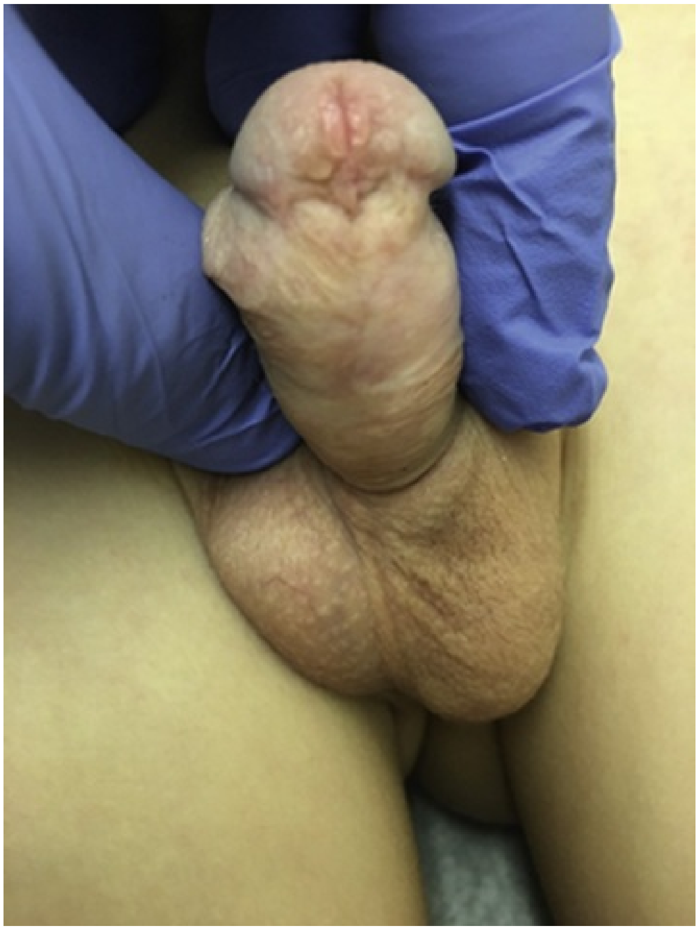

FIG. 45.40 Boy with a history of a two-stage repair resulting from a proximal hypospadias and severe ventral penile curvature. His meatus is located at the coronal margin, but his penis is straight and he voids without any spraying.

As we clamor to standardize our surgical interventions, we are limited until we can objectify our outcome measures across institutions. To this end, technology will play an increasing role. Preoperative, intraoperative, and postoperative videography with the potential for “crowd sourcing” can aid in severity assessment and long-term assessment of outcomes. Recording and cataloging of videotaped procedures, combined with artificial intelligence or machine learning, allows what was once a single surgeon's subjective assessment of a boy's outcome to be measured across thousands of patients. As personalized medicine continues to evolve and it becomes easier to perform routine genetic, proteomic, and microbiome analysis, one can imagine the potential for a refined physical and risk assessment for the boy while planning surgery. Those who take on these challenges will be the hypospadiologists of the future.

Etiology, Diagnosis, and Management of the Undescended Testis

Julia Spencer Barthold MD, Jennifer A. Hagerty DO

Introduction

Cryptorchidism, or undescended testis, is a common reproductive anomaly that is extensively studied yet incompletely understood. Testicular descent is a complex and prolonged event that is completed in the third trimester of gestation or soon after birth. The fetal structure that orchestrates descent of the testis, the gubernaculum, is anatomically well-characterized, but gaps in knowledge remain regarding its mechanical function during testicular descent. Genetic and/or environmental factors likely contribute to failure of testicular descent, but also these remain largely unknown. The available evidence suggests that susceptibility is complex and multifactorial, and may include both genetic factors and exposure to endocrine-disrupting chemicals (EDCs), potentially in combination. Cryptorchidism was traditionally considered a congenital anomaly identifiable at birth, but strong evidence now exists that an initial diagnosis well beyond the neonatal period is not uncommon. Clinically significant differences that affect long-term outcome, if any, between the acquired and congenital presentations of cryptorchidism remain obscure. Retractile testes may represent a milder form of the disease in some cases, conferring a higher risk for acquired cryptorchidism that is diagnosed later in childhood. Ultrasonography and other forms of imaging are rarely if ever needed for diagnosis, and hormonal therapy is no longer advocated as a first-line treatment for cryptorchidism. Present evidence supports surgery as the preferred treatment, with the specific approach depending on testicular palpability and position, size, patient age, and overall health status. Increasingly, primary scrotal and laparoscopic approaches are used and preferred. Suboptimal semen quality is common in bilateral cases, but can also occur in unilateral cryptorchidism, although paternity may be preserved. Risk for testicular germ cell tumor (TGCT) is increased in the affected, and to a lesser degree, contralateral testis but may be reduced by early surgery. Long-term outcome depends on laterality, age at treatment, and potentially, on the underlying etiology.

Definitions

As differing terminology is used to describe conditions related to normal and abnormal testicular descent and absence of a testis in the scrotum, we provide definitions for the following terms that are used throughout the chapter:

- ***Normal scrotal position*** has been defined as positioning of the midpoint of the testis at or below the midscrotum (Wohlfahrt-Veje et al., 2009). Although "high scrotal testes" are not routinely considered undescended by most clinicians, they have been included in the definition of undescended testis in some epidemiologic studies (Sijstermans et al., 2008). This is likely a heterogeneous group that includes stable descended testes that reside above the scrotal midpoint, retractile testes, and undescended "gliding" testes (Hack et al., 2007), which are not stable.
- ***Undescended testis*** or ***cryptorchidism*** is the absence of one or both testes in normal scrotal position and during initial clinical evaluation may refer to palpable or nonpalpable testes, which are either cryptorchid or absent. Testes may be arrested along the normal line of descent, or reside in an ***ectopic*** position outside the ipsilateral inguinal canal. Most absent testes are ***vanishing*** or ***vanished,*** present initially in development but lost as a result of vascular accident or torsion unilaterally ***(monorchia)*** or, very rarely, bilaterally ***(anorchia)*** (Abeyaratne et al., 1969).
- ***Agenesis*** refers to a testis that was never present, and therefore associated with ipsilateral müllerian duct persistence.
- ***Congenital cryptorchidism*** refers to a testis that is extrascrotal at birth.
- ***Acquired cryptorchidism*** is defined as a cryptorchid testis that was documented as scrotal at a previous examination.
- ***Recurrent cryptorchidism*** is defined as a cryptorchid testes that

was undescended at birth, descended spontaneously, and is subsequently extrascrotal.

- ***Secondary cryptorchidism*** and ***testicular retraction*** have been used to describe a testis that is suprascrotal after inguinal hernia repair or as a complication of orchidopexy, respectively. Testicular malposition after hernia repair could be caused by either primary maldescent or postoperative scarring.
- ***Retractile testes*** are scrotal testes that retract easily out of the scrotum but can be manually replaced in a stable scrotal position and remain there at least temporarily until there is recurrent stimulation. Testes that are significantly retractile, that is, those that rarely remain in a stable scrotal position (spontaneously or with manipulation) and/or are located at rest in the high scrotum may or may not be diagnosed as cases of acquired cryptorchidism on longitudinal examination.

Etiology

Embryology of Testicular Descent and Maldescent

Cryptorchidism represents a failure of testicular descent, which is in turn dependent on growth and hormonal function of the developing testis and its regulation of growth and function of the gubernaculum (Hutson et al., 2013, 2016; Virtanen and Toppari, 2014). Testicular descent is regulated by two Leydig cell hormones: insulin-like 3 (INSL3) via its receptor relaxin/insulin-like family peptide receptor 2 (RXFP2), and androgens (dihydrotestosterone [DHT] and testosterone) via the androgen receptor (AR). Descent also appears to require intact innervation of the gubernaculum by the genitofemoral nerve (GFN). Downstream effects and interactions, if any, between hormonal and neural pathways, are poorly defined. Altered expression or function of key molecules that participate in testicular and/or gubernacular development, as a result of genetic or environmental effects, likely contribute to cryptorchidism susceptibility.

Differentiation of the Testis

Gonadal differentiation is more complicated than the original concept of ovarian development as the default pathway. Activation of specific programs involving multiple genes is required for both male and female sex determination in mice (Capel, 2017; Rotgers et al., 2018; Sekido et al., 2013; Ungewitter and Yao, 2013). Although basic work has moved the field substantially forward in recent years, the mechanisms of cell-specific development in the testis remain incompletely understood (Svingen and Koopman, 2013). ***Sry*** **(sex-determining region on the Y chromosome) expression in the indifferent gonad triggers testicular development.** *Sry* “tips the balance” of antagonistic signaling between male and female pathways toward the male program (Capel, 2017) and is activated in part by steroidogenic factor 1 (SF1/*Nr5a1)*. In turn, SRY and SF1 proteins cooperate to promote prolonged expression of another transcription factor, *Sox9* (SRY box-containing 9), in pre-Sertoli supporting cells. SRY is important for Sertoli cell specification, but downstream testis-determining genes including *Sox9*, *Fgf9* (fibroblast growth factor 9), *Amh* (anti-Müllerian hormone), *Ptgds* (prostaglandin synthase), and likely others are required for Sertoli cell differentiation and proliferation (Kashimada and Koopman, 2010). Establishment of the Sertoli cell lineage is required for subsequent testicular cord formation. Studies in the fetal mouse indicate that patterning of the testis requires a temporal series of events that includes germ cell migration into the undiffererentiated gonad, and migration of interstitial cell precursors from the coelomic epithelium and the mesonephros (Combes et al., 2009; Cool et al., 2009; McClelland et al., 2012; Wainwright and Wilhelm, 2010).

In humans, gonads containing somatic and germ cells are first identified on the medial aspect of the urogenital ridge at 32 days postovulation (Hanley et al., 1999). At this sexually indifferent stage, the gonads and the internal and external genitalia are identical in males and females. Expression of *SRY* and *SOX9* transcripts begins at 40 days' gestation (Mamsen et al., 2017) and is followed by the histologic appearance of Sertoli cells (Ostrer et al., 2007). By 6 weeks' gestation, primordial germ cells (PGCs) migrate from the yolk sac, differentiate into gonocytes, and by 8 weeks are localized within the testicular cords (Culty, 2009). Gonocytes express c-KIT (mast/stem cell growth factor receptor Kit) beginning at 7 weeks, and their numbers increase further during the remainder of the first trimester (Ostrer et al., 2007). During the second trimester, three subpopulations of germ cells including gonocytes, intermediate spermatogonia, and prespermatogonia can be distinguished by immunostaining for specific markers (Gaskell et al., 2004). POU5F1 (POU domain class 5 homeobox 1, also known as OCT4) and c-KIT are expressed in the earlier lineages and disappear with loss of gonocytes by 20 weeks, and gain of MAGE-A4 (melanoma antigen, family A, 4) immunopositivity occurs with emergence of prespermatogonia (Culty 2009; Gaskell et al., 2004).

Two populations of Leydig cells exist in mammals, fetal and adult Leydig cells, which differ in appearance, function, and regulation (Martin, 2016; Teerds et al., 2015). Fetal Leydig cells (FLCs) arise from the coelomic epithelium and perivascular cells at the gonad-mesonephric border, which form interstitial Leydig cell progenitors (Rotgers et al., 2018). Recent evidence shows that these progenitors express AR and are regulated by androgens (Kaftanovskaya et al., 2015; Kilcoyne et al., 2014). FLC development is dependent on a wide variety of growth factors and developmental proteins and on paracrine interactions with Sertoli and peritubular myoid cells (reviewed in Martin, 2016; Rotgers et al., 2018). *Wt1* expression in mouse Sertoli cells contributes to proliferation and differentiation of peritubular myoid and Leydig cells (Wen et al., 2016). FLCs become active at 6 to 7 weeks, proliferate until about 15 weeks, and involute after 24 weeks (Codesal et al., 1990; Habert et al., 2001; O'Shaughnessy et al., 2007; Rotgers et al., 2018). Before the end of the first trimester of gestation, the external genitalia are completely masculinized, the testis cords are established, and subpopulations of both proliferating and degenerating germ cells exist. Sertoli and germ cell proliferation continues well into the second trimester (O'Shaughnessy et al., 2007).

Testicular Hormone Production

Hormonal function of the human fetal testis is critical for masculinization of the reproductive tract and testicular descent (Ivell et al., 2016). Activation of testicular hormone production occurs at discrete intervals during fetal, postnatal, and pubertal life (Fig. 46.1). In the fetus, Leydig cell development is divided into three phases: a proliferation and differentiation phase between 7 and 14 weeks, a maturation phase until 18 weeks, and an involution phase that continues until term (Svechnikov and Soder, 2008). Synthesis of testosterone by FLCs starts as early as 6 to 7 weeks and appears to be initially independent of gonadotropin stimulation. However, placental human chorionic gonadotropin (hCG) stimulates a peak in androgen production at 14 to 16 weeks, and the testis then becomes responsive to fetal luteinizing hormone (LH). Insulin-like 3 (INSL3) of Leydig cell origin is measurable in human amniotic fluid as early as 11 weeks, and production peaks at 15 to 17 weeks (Anand-Ivell et al., 2008, 2018; Bay et al., 2008; Ivell et al., 2016). Fetal Sertoli cells produce antimüllerian hormone (AMH; also called müllerian-inhibiting substance [MIS]) soon after they differentiate; the human fetal müllerian duct is responsive to AMH before 8 weeks, and the process of regression occurs between 9 and 10 weeks (Josso et al., 2006).

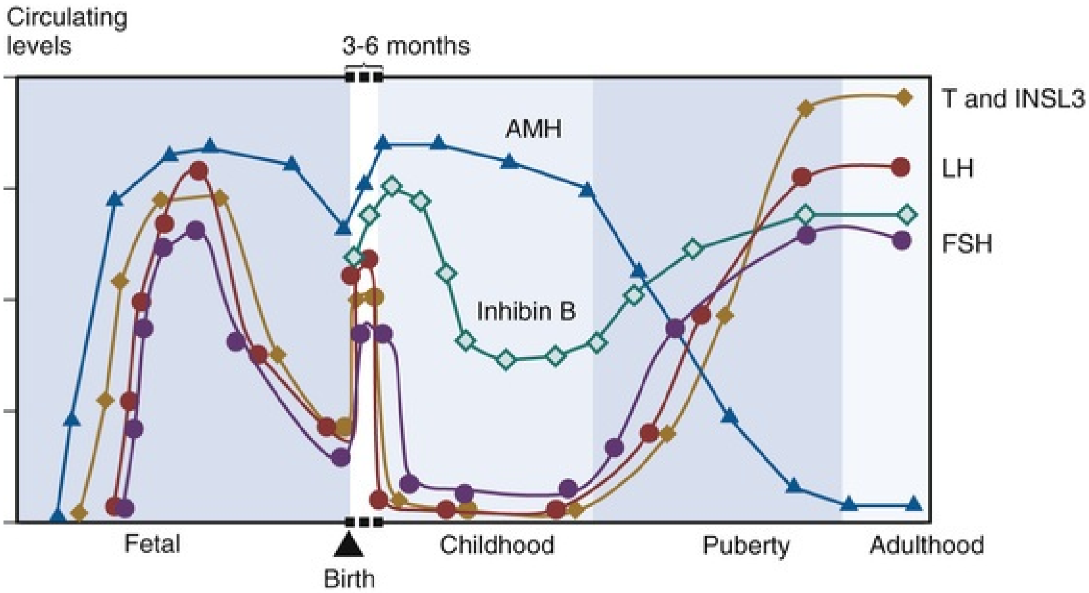

FIG. 46.1 Circulating male hypothalamic-pituitary-gonadal axis hormones from conception to puberty. Schematic view shows the rise in testosterone *(T),* insulin-like 3 *(INSL3),* luteinizing hormone *(LH),* follicle-stimulating hormone *(FSH),* and anti-Müllerian hormone *(AMH)* during early fetal life, secondary elevation of these hormones and of inhibin B soon after birth, and suppression of AMH at puberty. (From Grinspon RP, Ropelato MG, Bedecarras P, et al. Gonadotrophin secretion pattern in anorchid boys from birth to pubertal age: pathophysiological aspects and diagnostic usefulness. *Clin Endocrinol (Oxf)* 76(5):698–705, 2012b).

Steroid hormones exert their effects via sex steroid receptors in the reproductive tract and testis. AR and estrogen receptor beta (ERβ) are expressed in the undifferentiated gonad at 7 weeks, although their role in testis development is unclear (Boukari et al., 2007; Shapiro et al., 2005). AR is present primarily in peritubular myoid cells and in some Leydig and interstitial cells, but is absent in Sertoli cells during early development. Lack of AR expression in fetal and early postnatal Sertoli cells is physiologically important because its presence would allow inappropriate androgen-induced inhibition of AMH production and precocious simulation of spermatogenesis (Boukari et al., 2009; Rey et al., 2009). ERβ expression in fetal testis is observed in germ, peritubular myoid, Sertoli, and some Leydig cells, and expression of estrogen receptor alpha (ERα) is limited (Shapiro et al., 2005) or absent (Boukari et al., 2007) in human fetal testis. Concomitant expression of aromatase during the same time frame suggests that locally produced estrogen may play a role in testis development.

Reactivation of the hypothalamic pituitary gonadal axis occurs during the neonatal period, a phenomenon known as “mini-puberty” (see Fig. 46.1), with cross-sectional data suggesting that peak hormone levels occur at 1 to 3 months of age. Serum LH and follicle-stimulating hormone (FSH) levels rise postnatally, followed by increases in testosterone, AMH, and inhibin B (INHB), and INSL3 levels are high in both cord blood and at 3 months of age (Aksglaede et al., 2010; Andersson et al., 1998; Bay et al., 2007; Bergada et al., 2006). However, individual longitudinal data indicate that postnatal urinary LH, FSH, and testosterone levels peak earlier, at or before 1 month of age, and are more pronounced in preterm boys (Kuiri-Hanninen et al., 2011). Studies of the androgen insensitivity syndrome provide evidence that the postnatal hormone surge occurs as a response to maternal androgen withdrawal, resulting in secondary upregulation of hypothalamic and pituitary hormone secretion (Quigley, 2002). FLCs regress after birth followed by emergence of a neonatal Leydig cell population at 2 to 3 months of age that regresses by the end of the first year of life (Prince, 2001). As postnatal hormonal levels wane, FLCs either degenerate or regress to immature, partially differentiated Leydig/interstitial cells that are less responsive to LH.

The postnatal hormone surge is accompanied by increased testicular volume primarily caused by Sertoli and germ cell proliferation (Grumbach, 2005). Several studies show significant growth of testes during the neonatal period (Berensztein et al., 2002; Kuijper et al., 2008; Main et al., 2006a, 2006b), and increased testicular growth rate and HPG axis activation are correlated in preterm boys (Kuiri-Hanninen et al., 2011), suggesting that growth is a direct response to hormonal stimulation. Sertoli cell proliferation continues in the first year of life and is a major determinant of ultimate testicular size (Sharpe et al., 2003). Undifferentiated germ cells, called *prespermatogonia*, *prospermatogonia*, or *gonocytes* (Culty, 2013; McCarrey, 2013), migrate to the basement membrane after birth and become established as undifferentiated type A spermatogonia. In humans and primates, type adult dark (Ad) and adult pale (AP) spermatogonia include a subpopulation of spermatogonial stem cells (Griswold and Oatley, 2013; Hermann et al., 2010). Because migration occurs in a similar time frame to HPG axis activation, a relationship is presumed (Hadziselimovic et al., 1986, Hutson et al., 2012), but regulation of this important event remains poorly understood. Factors known to regulate migration of prespermatogonia/gonocytes include platelet-derived growth factor, thyroid hormone, and cell adhesion molecules (Basciani et al., 2008; Oatley et al., 2011; Orth et al., 2000; Tres and Kierszenbaum, 2005) as well as other nonhormonal factors (Barthold, 2015; Mecklenburg and Hermann, 2016), which in turn may be regulated by HPG axis hormones. However, a role, if any, for androgens in gonocyte migration and differentiation is controversial. Fetal gonocytes express AR, and androgens inhibit their proliferation, but there is no evidence that androgens affect neonatal gonocyte proliferation, migration, or differentiation (Li et al., 2015; Manku and Culty, 2015; Merlet et al., 2007). If migration fails to occur, prespermatogonia/gonoctyes may be at increased risk for apoptosis or future malignant transformation (Rajpert-de Meyts and Hoei-Hansen, 2007; Rajpert-De Meyts et al., 2016).

Gubernacular Development and Testicular Descent

The physiology of normal testicular descent and the etiology of abnormal descent in humans remain incompletely understood, and the morphologic events have been well-studied in mammals. Knowledge of the regulation of testicular descent is inferred from studies of human diseases that include cryptorchidism and/or from animal models of the disease.

The human indifferent gonad develops adjacent to and becomes suspended from the mesonephros, which has replaced the pronephros by 5 weeks (Lemeh, 1960). A rudimentary cranial mesonephric ligament connects to the diaphragm, disappearing by 13 weeks as the mesonephros regresses (Barteczko and Jacob, 2000). Recent human fetal studies confirm that there is no direct connection between the gonad and this ligament (Bouzada et al., 2017); therefore it appears that no “cranial gonadal ligament” exists in humans as noted in other species. However, like rodents, the gubernaculum is attached proximally to the epididymis, and not directly to the testis (Bouzada et al., 2017; Favorito et al., 2014). Using fixed sections, Barteczko and Jacob observed an “inner” or relative transabdominal descent of the human testis from vertebral levels C7–T8 to T9–L3 between 5 and 7 weeks, and to the sacral level by 10 weeks; using dissections, others described the testis at the level of L4 by 7 weeks (Lemeh, 1960) or always “close to the groin” (Wyndham, 1943). Other human fetal studies confirm that the testis remains close to the internal inguinal ring from 10 weeks onward (Bouzada et al., 2017; Favorito et al., 2016), suggesting that if true transabdominal descent occurs, it is unrelated to swelling or hormonal stimulation of the gubernaculum (see later). Caudal movement of the ovary is prevented by the ovarian ligament and development of the müllerian ducts.

Barteczko and Jacob (2000) described five major phases of testicular descent in the human fetus (Fig. 46.2). In **Phase 1** (5 weeks), the caudal mesonephros contacts the future gubernaculum at the internal inguinal ring. In **Phase 2**, the genitofemoral nerve (GFN) is seen to accompany the newly formed gubernaculum (abdominal, interstitial, and subcutaneous portions) and processus vaginalis (7 weeks); subsequently, growth of the gubernaculum, deepening of the processus vaginalis, and extension of cremaster muscle fibers into the interstitial gubernaculum occurs (8 to 10 weeks). In **Phase 3** (10 to 14 weeks), growth of the testis and regression of the müllerian ducts and mesonephros occurs; the gubernaculum is visible as a thin cord in both sexes and begins its swelling phase in males beginning at 12 weeks, after the testis is already located at the internal inguinal ring. In **Phase 4** (14 to 20 weeks)**,** swelling of the gubernaculum, further development of the cremaster muscle, and migration of the processus vaginalis produce widening of the inguinal canal. In **Phase 5** (20 to 28 weeks), release of the distal subcutaneous attachment of the gubernaculum and transinguinal passage of the testis occur. Further caudal movement of the testis into the scrotum up until the time of birth is accompanied by regression of the gubernaculum.

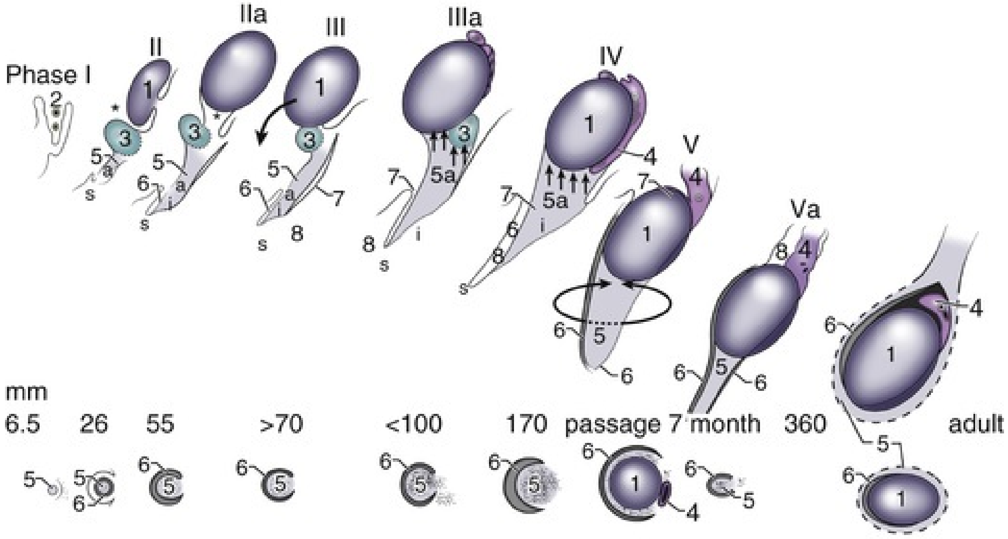

FIG. 46.2 Overview of human testicular descent. Sagittal view *(above)* and transverse sections *(below)*; *1,* gonad; *2,* mesonephros; *3,* Wolffian and müllerian ducts; *4,* vas deferens/epididymis; *5,* gubernaculum: *a,* abdominal; *i,* interstitial; *s,* subcutaneous part; *6,* processus vaginalis; *7,* internal inguinal ring; *8,* external inguinal ring. *Straight arrows* (phase I) show the ventral side; *Asterisks* (I–IIIa) show the link between the caudal pole of the testis and the dorsal mesenchyme of the genital ducts; *curved arrow* (III) shows the direction of testicular migration; *short arrows* (IIIa–IV) indicate attachment between the testis or epididymis and gubernaculum; *oval arrowline* (V) indicates no connection between the boltlike gubernaculum and neighboring structures. (Modified from Barteczko KJ,

Jacob MI. The testicular descent in human. Origin, development and fate of the gubernaculum Hunteri, processus vaginalis peritonei, and gonadal ligaments. *Adv Anat Embryol Cell Biol* 156[III–X]:1–98, 2000).

Detailed anatomic observations by Barteczko and Jacob (2000) throughout gestation help clarify some aspects of human testicular descent. For example, apparent transabdominal movement of the testis occurs before sexually dimorphic changes in the gubernaculum and is therefore not a male hormone-specific event. The subsequent male-specific swelling of the gubernaculum parallels the peak in Leydig cell secretion of testosterone (14 to 16 weeks) and INSL3 (15 to 17 weeks). The GFN precedes and accompanies the gubernaculum and developing processus vaginalis in both sexes beginning at an early stage (7 weeks), and both smooth (in the abdominal portion) and skeletal (in the interstitial and subcutaneous portion) muscle fibers are present within these three segments of the gubernaculum. Both muscle types were also observed by other (Lemeh, 1960; Wyndham, 1943) but not all (Bouzada et al., 2017; Costa et al., 2002; Heyns, 1987; Niikura et al., 2008) observers. However, studies of the in situ gubernaculum beginning at 20 weeks clearly show the presence of peripheral and centrally located striated muscle bundles (Barteczko and Jacob, 2000; Niikura et al., 2008) and infiltration of the gubernaculum by the GFN (Tayakkanonta, 1963). Controversy exists as to whether skeletal cremaster muscle fibers originate from abdominal wall musculature or from within the gubernaculum itself (Barteczko and Jacob, 2000; Niikura et al., 2008; van der Schoot, 1996), but their unique innervation and recent studies of transgenic mice (see the following) suggest the latter.

Swelling of the gubernaculum, caused by cellular proliferation and production of extracellular matrix, is required for enlargement of the inguinal canal and testicular passage (Heyns, 1987). Once the canal is created, unknown mechanical factors trigger a typically rapid transinguinal passage of the testis. The gubernaculum is unattached distally during and after transinguinal passage (Fig. 46.3), and settling of the gubernaculum and testis into the preformed scrotum is gradual. The scrotum itself develops from genital swellings that are first visible at 7 weeks and fuse by 10 to 12 weeks in response to circulating dihydrotestosterone. Passage of the testis into the inguinal canal rarely occurs before 22 weeks in the human fetus, and the majority of testes are scrotal after 27 weeks; time spent in the inguinal canal seems to be limited for the majority of human fetal testes (Heyns, 1987; Sampaio et al., 1998). The rapidity of transinguinal testicular transit, early innervation of the gubernaculum in human fetuses (Barteczko and Jacob, 2000), significance of the GFN in rodents (Hutson and Hasthorpe, 2005), and the complex anatomic distribution of cremaster muscle in and around the gubernaculum (Harnaen et al., 2007; Niikura et al., 2008) suggest that neuromuscular forces are required for testicular descent.

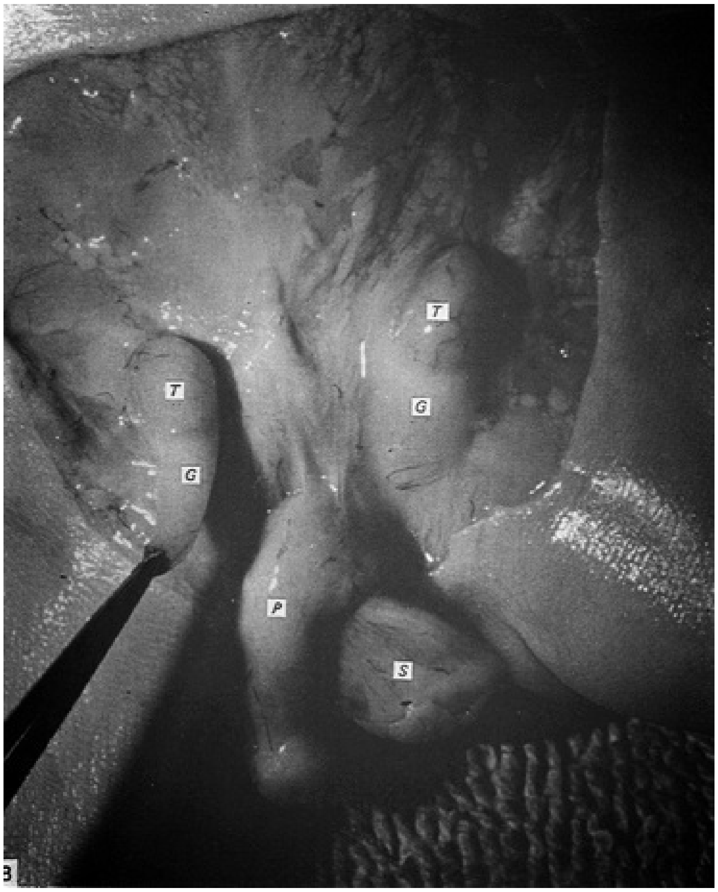

FIG. 46.3 The distally unattached human gubernaculum just before transinguinal passage. Human fetus at 25 weeks of gestation (215-mm crown-rump length) just before transinguinal testicular descent. *T,* Testis; *G,* gubernaculum; *P,* penis; *S,* scrotum. (From Heyns CF. The gubernaculum during testicular descent in the human fetus. *J Anat* 153:93–112, 1987.)

Regulation of Testicular Descent

Direct evidence for hormonal control of testicular descent is based on studies in animal models, primarily rodents. The relevance of rodent data to humans has been questioned because of anatomic differences, which in mice and rats include a less prominent interstitial gubernaculum, a cranial gonadal ligament, a well-developed intrinsic cremaster muscle located in the periphery of the gubernaculum, an absent inguinal canal, and failure of closure of the processus vaginalis (Wensing, 1988). However, the developing processus vaginalis and cremaster muscle are sufficiently anatomically similar among species to warrant translational studies using rodent models (Harnaen et al., 2007; van der Schoot, 1996), and their normal development is essential for testicular descent.

Animal models and indirect clinical evidence strongly support an essential role for the testicular hormones INSL3 and androgens in the regulation of testicular descent. Transgenic or spontaneous rodent strains with inactivation of *Insl3*, *Rxfp2*, or *Ar* are cryptorchid (Adham et al., 2000; Overbeek et al., 2001; Zimmermann et al., 1999) as are boys with abnormalities of androgen synthesis or action (Barthold et al., 2000; Foresta et al., 2008; Gaspari et al., 2011). According to a paradigm first developed by Hutson (1985), testicular descent occurs in separate transabdominal and transinguinal phases, regulated by a nonandrogenic factor (now known as INSL3) and by androgens via the GFN, respectively (Hutson, 1985; Hutson and Hasthorpe, 2005). However, animal models show that INSL3 and androgen synergistically stimulate cellular proliferation and growth of the gubernaculum (Adham et al., 2000; Emmen et al., 2000; Kubota et al., 2002) and that both INSL3 binding and AR expression are present before and during the swelling phase of the fetal rat gubernaculum (Staub et al., 2005). Moreover, INSL3 and testosterone levels peak after 12 weeks in the human fetus, concurrent with gubernacular swelling, and apparent transabdominal testicular descent, if it does occur, happens earlier, during the third month of gestation (Barteczko and Jacob, 2000; Koskimies et al., 2003; McKinnell et al., 2005). In mice, INSL3 signaling also promotes development of the processus vaginalis, and androgen signaling causes regression of the cranial gonadal ligament (Adham and Agoulnik, 2004; Adham et al., 2002; Koskimies et al., 2003), a structure that does not exist in the human fetus. Therefore, the testis remains stable as the gubernaculum swells (the “outgrowth” phase) and facilitates creation of the processus vaginalis, and then descends as the gubernaculum shrinks (the “regression” phase), as described over 30 years ago (Heyns 1987; Wensing 1988). INSL3 and androgens appear to regulate both phases of gubernacular development and descent.

Both INSL3/RXFP2 and AR also appear to directly regulate myogenic differentiation of the cremaster. Conditional deletion of *Rxfp2* or *Ar* in gubernacular mesenchymal cells, before their differentiation into muscle (Robbins et al., 2016), disrupts testicular descent (Kaftanovskaya et al., 2011, 2012). In gubernaculum-specific *Rxfp2*–/– transgenic mice, aberrant muscle cells are visible within the developing mesenchymal core of the gubernaculum, and the cremaster muscle fails to develop normally, suggesting that proliferation, migration, and patterning of muscle precursors depends on INSL3/RXFP2 signaling. Moreover, AR-positive cells are mislocalized in the gubernaculum of conditional *Rxfp2*–/– mouse fetuses, suggesting interaction between the RXFP2 and AR pathways. The defect in cremaster development is less severe with conditional deletion of *Ar* in gubernacular mesenchyme, however, muscle organization and growth are impaired, expression of muscle-specific markers is altered, and testicular descent fails to occur (Kaftanovskaya et al., 2012).

The definition of pathways and mechanisms of gubernacular development and testicular descent downstream of hormone signaling are provided by transgenic mouse models and human syndromes with phenotypes that include cryptorchidism (Barthold 2008; Foresta et al., 2008). A theme that again emerges from these studies is the importance of myogenesis in gubernacular development. In mice, transgenic inactivation of genes including *Notch1* and several involved in Wnt pathway signaling including *Ctnnb1, Sfrp1, Sfrp2, Wnt5a,* and *Ror2* results in marked disruption of fetal muscle patterning (Chawengsaksophak et al., 2012; Kaftanovskaya et al., 2011; Warr et al., 2009). Gene expression in fetal rat gubernaculum after stimulation by dihydrotestosterone (Barthold et al., 2013) or INSL3 (Johnson et al., 2010) also supports activation of Wnt pathways by both hormones and strong overlap in their transcriptional response. Transgenic deletion of either of two homeobox genes, *Hoxa10* and *Hoxa11,* is associated with isolated cryptorchidism in mice (Potter and Branford, 1998; Satokata et al., 1995), with evidence for delayed muscle development in the *Hoxa11* gubernaculum (Harisis et al., 2013). Also, the cremaster muscle is overdeveloped and associated with retractile testes in *Esr1* knockout mice (Donaldson et al., 1996). Other transgenic rodent models that include the cryptorchid phenotype provide insight into pathways required for testicular descent. These include targeted deletions of *Tgfb2* (Sanford et al., 1997), *Arid5b* (Lahoud et al., 2001), *Wt1* (Kaftanovskaya et al., 2013), *Ptgds* (Philibert et al., 2013), *Loxl1* (Wood et al., 2009), *Adamts16* (Abdul-Majeed et al., 2014), *Crkl* (Haller et al., 2017), *Lifr* (Kosfeld et al., 2017), and *Vamp7* (Tannour-Louet et al., 2014), and spontaneous mutations of *Ptch1* (Sweet et al., 1996) and *Bmp5* (Green 1968).

Based on extensive rodent studies, Hutson et al. showed that gubernacular innervation by the GFN is essential for its function, and they propose that release of calcitonin gene-related peptide (CGRP) from GFN sensory nerve endings stimulates development and function of the gubernaculum (Chan et al., 2009; Yamanaka et al., 1993). They further suggest that androgens indirectly regulate testicular descent via receptors located in mesenchymal tissue along the mammary line (reviewed in Hutson et al., 2016). This theory conflicts with data indicating that functional AR is present within the gubernaculum (reviewed in Robbins et al. in re-review). Although a role for CGRP release from the GFN in human testicular descent remains undefined, it is clear that the fetal gubernaculum contains and is surrounded by muscle and is innervated by the GFN beginning as early as 7 weeks (Barteczko and Jacob, 2000; Lemeh, 1960; Niikura et al., 2008; Tayakkanonta, 1963). Moreover, genome-wide association data suggest that *RBFOX* genes, which encode RNA-binding proteins that regulate production of CGRP, are associated with clinical cryptorchidism (Wang et al., 2018a).

In summary, the gubernaculum develops in both sexes beginning early in the second month of gestation, and the testicular hormones INSL3 and androgen stimulate development of the gubernaculum and testicular descent in the second and third trimesters. Enlargement and migration of the gubernaculum are key events that facilitate and direct caudal movement of the testis. INSL3 and androgens appear to synergistically target cellular proliferation, migration, and muscle patterning within the gubernaculum, in part via Wnt signaling. A consistent theme in experimental models of cryptorchidism is altered myogenesis of the cremaster, suggesting an important role in the process of testicular descent.

Epidemiology

Cryptorchidism is one of the most common congenital anomalies, occurring in 1% to 9% of full-term and 1% to 45% of preterm newborn males (Barthold et al., 2016b; Gurney et al., 2017b; Sijstermans et al., 2008). Although 80% to 85% of cases are isolated, or nonsyndromic (Barthold et al., 2016b), cryptorchidism is also a component of almost 500 syndromes causally linked to 387 genes within 414 loci, according to the most current data available in Online Mendelian Inheritance in Man (OMIM; https://www.ncbi.nlm.nih.gov/omim). The most common associated syndromes are reviewed elsewhere (Foresta et al., 2008; Virtanen and Toppari, 2008), but a common subset of syndromic cases is associated with hormonal defects of the hypothalamic-pituitary-gonadal (HPG) axis.

Congenital Cryptorchidism

Studies of the prevalence of isolated cryptorchidism at birth are complicated by confounding factors that include subjectivity of the examination, differences in the definition of undescended testis (inclusion/exclusion of high scrotal testes), study populations, and experimental design (Sijstermans et al., 2008). Although most studies support a prevalence at birth of 2% to 4% and at 3 months of age of 1% to 2%, this varies geographically, with frequency as high as 9% in some studies (Boisen et al., 2004; Virtanen and Toppari, 2008), supporting the possibility of an increase over time. However, other data have failed to show reproducible upward or downward trends in frequency (Abdullah et al., 2007; Barthold et al., 2016b; Bonney et al., 2009; Cortes et al., 2008; Gurney et al., 2017b; Sijstermans et al., 2008; Wagner-Mahler et al., 2011). Cryptorchidism is more common in Caucasian as compared with non-Caucasian populations (Gurney et al., 2017b).

The reported frequency of spontaneous testicular descent after birth varies among series, likely because of similar confounding factors, most notably variable inclusion of boys with high scrotal testes. In several population-based, prospective studies, the frequency of spontaneous descent by 3 months of age in boys identified as cryptorchid at birth was reported as 50% to 87% (Berkowitz et al., 1993; Ghirri et al., 2002; Mavrogenis et al., 2014; Radpour et al., 2007; van der Plas et al., 2013b; Wagner-Mahler et al., 2011;Wohlfahrt-Veje et al., 2009). In smaller cohorts, spontaneous descent occurred in significantly more Danish (68%) than Finnish (45%) boys at 3 months of age, possibly attributable to increased severity of the disease in the latter group (Suomi et al., 2006). In a group of boys followed closely from birth, spontaneous descent was common before 2 months of age (Kollin et al., 2013). Extrascrotal testes were less likely to descend by 1 year of age (50%) than high scrotal testes defined as cryptorchid at birth (87.5%) (Acerini et al., 2009). On the other hand, of 95 cryptorchid infants referred to a urology practice, spontaneous descent occurred subsequently in 16% and 0% of those presenting before and after 6 months of age, respectively (Wenzler et al., 2004). The lower rate of descent in this series could be related to exclusion of many cases of early neonatal descent, and a higher degree of cryptorchidism severity in this referral population. The long-term risk for recurrent cryptorchidism is not well defined, but in two large longitudinal series, re-ascent occurred in 10% and 22% of boys, usually between

1 and 5 years of age (Kollin et al., 2013; Wagner-Mahler et al., 2011).

Acquired Cryptorchidism

In the past, cryptorchidism was considered a congenital anomaly identifiable at birth. First reported 40 years ago (Myers and Officer, 1975), acquired cryptorchidism, or testes that are diagnosed as cryptorchid after apparent full descent at birth or in the neonatal period, is now an established clinical entity (Acerini et al., 2009; Barthold and González, 2003; Hack et al., 2012; Taghizadeh et al., 2008; Wohlfahrt-Veje et al., 2009). **Acquired cryptorchidism most likely represents a milder presentation of congenital cryptorchidism that escapes detection in infancy.** Compared with cases diagnosed at birth, these are diagnosed at an average age of 8 to 11 years, and are more likely to be in a lower position distal to the inguinal canal, and accompanied by a closed processus vaginalis and a normal epididymis. The reason for a later diagnosis remains unknown; theories include presence of a fibrous remnant of the processus vaginalis that tethers or foreshortens the cord over time, or mobility of the testis within an open sac (Keys and Heloury, 2012). However, it is most likely that the testis is incompletely descended from birth, as many are located in a lateral (ectopic) position within the superficial inguinal pouch (Barthold and González, 2003; van Brakel et al., 2011). These testes may be highly mobile and initially appear descended until somatic growth results in relative widening of the distance between testis and scrotum (Agarwal et al., 2006; Redman, 2005). Acquired cryptorchidism is more common in boys with proximal hypospadias (Itesako et al., 2011; Tasian et al., 2010) and is also associated with abnormal germ cell development (Rusnack et al., 2002) and subfertility risk (van Brakel et al., 2014).

Some boys with retractile testes are more likely to develop acquired cryptorchidism, although retractile testes are common in normal populations. In a hospital-based study of unselected boys, the testis was initially suprascrotal on examination (retractile) in up to 30% of boys at 4 years and 10% of boys 4 to 12 years of age, but it was intrascrotal in all boys older than 12 years of age (Farrington, 1968). In population-based studies of healthy boys, retractile testes were present in 11% to 15% of boys up to 11 years of age (Goede et al., 2011; Wohlfahrt-Veje et al., 2009) and 4% of boys 7 to 12 years of age (Inan et al., 2008). Both prospective and retrospective studies of the natural history of retractile testes support the concept that a subset of these becomes undescended over time (Keys and Heloury, 2012). However, a selection bias exists in studies of the risk for cryptorchidism in boys with retractile testes, as those referred for follow-up by specialists are likely those with the most severe retractility. For example, Wyllie (1984) prospectively studied a cohort of 100 boys with unilateral retractile testis and identified 64 cases in which testicular position, as documented by the distance between the pubic tubercle and mid-testis, and/or testicular size, as estimated by orchidometer, was reduced after 5 years of follow-up. Orchidopexy was performed in 45 of these cases, although specific documentation of testicular position and size as indications for surgery were not reported. Retrospective case series report that cryptorchidism is diagnosed in up to 7% to 32% of boys with retractile testes followed a mean of 2.2 to 3.8 years by the same observer(s) (Agarwal et al., 2006; La Scala and Ein, 2004; Stec et al., 2007). However, in a prospective study of 1072 boys, 520 of whom were followed from birth to latest follow up at 4.5 to 10 years of age, only 2.6% with retractile testes developed ipsilateral cryptorchidism, although an additional 13.5% developed contralateral or secondary cryptorchidism (Wohlfahrt-Veje et al., 2009).

Although these data suggest an association between retractile testes and cryptorchidism, the nature of this association may reflect either difficulty in distinguishing the two entities or an increased risk for acquired cryptorchidism in boys with testicular retractility. In patients with retractile testes, some who underwent orchidopexy for social reasons, pathologies associated with cryptorchidism were also found, suggesting a continuum between the two entities. These included reduced testicular volume (Goede et al., 2011), a higher incidence of ipsilateral patent processus vaginalis and epididymal anomalies (Anderson et al., 2016), and altered cremaster muscle innervation (Favorito et al., 2018).

The true prevalence of acquired cryptorchidism is incompletely defined, because longitudinal data that provide documentation of prior scrotal position are limited, and address only the first few years of life. In one study, 742 infants were followed with serial examinations for 2 years after birth with complete follow-up in 326 (Acerini et al., 2009). The prevalence of extrascrotal testes was 2.7% at birth (27% nonpalpable, surgical findings not reported), and 0.2%, 1.8%, 0.3%, and 0% of testes in the studied population became extrascrotal at 3, 12, 18, and 24 months, respectively. The number of suprascrotal testes diagnosed at birth in this series (10) was the same as the number diagnosed subsequently (10), although almost one-half of the boys were lost to follow-up during the study. Including high scrotal testes, a total of 5.7% were identified as cryptorchid at birth and 1% to 4% rose to a high scrotal position with each follow-up visit. In another study, 1072 boys were followed with serial examinations from birth to 4.5 to 10 years of age, with complete follow-up in 500 (Wohlfahrt-Veje et al., 2009). The prevalence of congenital cryptorchidism (including high scrotal testes) was 9% at birth but dropped to 1% at 18 months, and 8 (1.6%) acquired cases were observed during follow up, suggesting that the prevalence of persistent congenital and acquired forms of cryptorchidism is similar. Retrospective series also suggest that acquired cryptorchidism is common, but cannot reliably differentiate true acquired cases from delayed referral of congenital cases (Barthold et al., 2012; Guven and Kogan, 2008; Hack et al., 2012; Jensen et al., 2011; van der Plas et al., 2013b). Delayed intervention may have adverse effects, therefore serial physical examination is recommended to accurately determine testicular position and identify cases of acquired cryptorchidism in boys with retractile testes.

Pathogenesis

The specific cause of cryptorchidism is unknown in most cases, but indirect evidence suggests that the disease is heterogeneous and most likely the result of multiple genetic and environmental risk factors. The most consistent risk factors for cryptorchidism occurrence are prematurity and/or low birth weight for gestational age, familial factors related to the maternal environment and/or rare genetic variants, maternal diabetes, and maternal smoking (Arendt et al., 2018; Barthold et al., 2016b; Bay et al., 2011; Brouwers et al., 2012; Damgaard et al., 2008; Gurney et al., 2017b; Jensen et al., 2010b, 2012). Maternal obesity or increased BMI was associated with cryptorchidism in large population-based studies but not in a meta-analysis of primarily smaller case-control studies, implying variability among populations (Arendt et al., 2018; Kjersgaard et al., 2018; Zhang et al., 2015). Studies of isolated, or nonsyndromic cryptorchidism do not suggest strong genetic risk at large effect genomic loci, but rather a multilocus, complex pattern of genetic susceptibility. Also, available human data have identified few clear and consistent exposures associated with the disease, although animal models suggest that certain environmental EDCs, potentially in combination, may contribute to cryptorchidism risk.

Genetic Susceptibility

Family studies of cryptorchidism suggest that the disease is heritable, but that susceptibility is likely polygenic and multifactorial. Clustering of cryptorchidism has been reported in a number of families affecting multiple individuals in the same generation, but the phenotype is variable (Czeizel et al., 1981; Minehan and Touloukian, 1974; Pardo-Mindan et al., 1975; Savion et al., 1984). Extended pedigrees were not usually examined, but autosomal dominance with reduced penetrance was most often cited as the probable mode of inheritance. Population case-control studies also support genetic contribution to the disease. Familial aggregation suggesting moderate genetic risk was reported in a recent large cohort study of greater than 1 million male births in the Netherlands based on extensive hospital registry data (Schnack et al., 2008). Recurrence risk ratio was 10.1 in twins, 3.5 in brothers, and 2.3 in offspring and was significantly higher in maternal than in paternal half-brothers. Another population-based study in Denmark, using different methodology, identified greater concordance rates of cryptorchidism diagnosis in maternal (6%) than in paternal (3.4%) half-brothers and in dizygotic (24%) and monozygotic (27%) twins relative to brothers (9%) (Jensen et al., 2008). However, when the analysis was limited to cases of persistent cryptorchidism treated surgically, concordance rates were 7.5% in brothers, 17% in dizygotic twins, and 27% in monozygotic twins. These observations suggest that environmental effects and/or maternal factors contribute to the risk for cryptorchidism in Denmark. Previous smaller studies reported a 5- and 7- to 10-fold increased prevalence in fathers and brothers, respectively, of affected as compared with unaffected subjects, and some also support the possibility that maternal factor(s), or X-linked risk alleles, influence expression of the disease (Barthold et al., 2012; Czeizel et al., 1981; Elert et al., 2003; Jensen et al., 2008; Jones and Young, 1982).

The most promising gene candidates for nonsyndromic cryptorchidism based on animal studies are *INSL3* and *RXFP2*. However, DNA coding variants within these genes are rare, identified in only 0.6% to 1.8% and 1.6% to 2.9% of persistently cryptorchid males, respectively (Foresta et al., 2008). Notably, some of these variants are associated with a range of phenotypes that include unilateral/bilateral and persistent/spontaneously resolving presentations, and apparently deleterious mutations may exist in normal family members, as noted for an *INSL3* mutation showing reduced receptor activation (El Houate et al., 2007). More than 1500 cryptorchidism cases have been screened for mutations in *INSL3*, but of 10 exonic variants identified in cases but not controls, few are clearly functional (Bay et al., 2011; Ferlin et al., 2008; Foresta et al., 2008). A nonsynonymous polymorphism of the *RXFP2* gene, T222P, was considered a strong etiologic candidate for cryptorchidism based on absence in normal controls and in vitro studies showing curtailed cell membrane localization and activation of the abnormal receptor (Bogatcheva et al., 2007). However, cases and controls in other European populations show a similar frequency of the *T222P* allele (Ars et al., 2011; Nuti et al., 2008). Although these data suggest that mutations of *INSL3* and *RXFP2* are infrequent in cases of cryptorchidism, regulatory variation in noncoding regions, or copy number variants (CNVs) that alter transcript or protein expression levels may exist, but have not been studied.

Analysis of other potential candidate genes for human cryptorchidism has failed to yield consistent results across populations. Two homeobox genes are strong candidates based on findings of isolated cryptorchidism in transgenic mice (Hsieh-Li et al., 1995; Rijli et al., 1995; Satokata et al., 1995), but associations between variants in these genes, *HOXA10* and *HOXA11*, and cryptorchidism have not been consistent (Bertini et al., 2004; Chavez-Saldana et al., 2018; Cheng et al., 2017; Kolon et al., 1999; Wang et al., 2007). Studies of polymorphic trinucleotide (CAG and GGN) repeats of AR in cryptorchidism have also shown varying results, but a recent meta-analysis of 8 studies comprising 321 cases and 784 controls supports association with longer AR repeat lengths in Caucasians (Wang et al., 2018b). A specific haplotype of the gene encoding estrogen receptor alpha *(ESR1)* appears to be associated with cryptorchidism, specifically in Asians but not in Caucasians (Galan et al., 2007; Lo Giacco et al., 2011; Tang et al., 2011; Yoshida et al., 2005; Wang et al., 2008). Microdeletions of the Y chromosome have also been studied in cryptorchid children and previously cryptorchid men, with no consistent association observed (Gurbuz et al., 2008; Mamoulakis et al., 2013a). *NR5A1*, which encodes steroidogenic factor 1 (SF1), a transcription factor that regulates expression of *INSL3*, *RXFP2*, and steroidogenesis genes, was associated with cryptorchidism in 72 cryptorchid Japanese males (Wada et al., 2006), but not in a larger population of 275 European males, although a rare variant was enriched in previously cryptorchid men with severe spermatogenic impairment (Ferlin et al., 2015). An association between aryl hydrocarbon receptor–associated genes and cryptorchidism was also noted in a single study (Qin et al., 2012). No cryptorchidism-associated variants were identified in the sex hormone–binding globulin gene *(SHBG)* or in genes associated with hypogonadotropic hypogonadism (HH) (Laitinen et al., 2011; Mamoulakis et al., 2013b). Differences among series may relate to small, insufficient sample sizes (most single series include less than 100 cases), and heterogeneity may explain the lack of replication in other population groups.

Limited available data from unbiased genome-wide studies identified rare CNVs in novel genes including *VAMP7*, *OTX1*, and *CRKL* associated with cryptorchidism, which were subsequently validated in knockout mice (Haller et al., 2017; Jorgez et al., 2014; Tannour-Louet et al., 2014). In contrast, genome-wide association studies (GWAS) have failed to identify a cryptorchidism-associated single nucleotide polymorphism (SNP) that passed the threshold of genome-wide significance ($P < 5 \times 10^{-8}$) and could be validated in an independent population. Although underpowered, a study of 488 men with at least one of the four phenotypes comprising the so-called *testicular dysgenesis syndrome (TDS)* (Sharpe and Skakkebaek, 2008) including infertility, cryptorchidism ($n = 138$), hypospadias, and/or TGCT (Dalgaard et al., 2012) did not identify any SNP passing this stringent threshold. Using a systems biology approach to map less significant signals into functional pathways, the authors identified transforming growth factor beta receptor 3 *(TGFBR3)*, a gene associated with transient Leydig cell dysgenesis in knockout mice (Sarraj et al., 2010), as a potential locus associated with cryptorchidism and TGCT in both discovery and replication cohorts. The TGFBR3 protein is expressed in FLCs (Dalgaard et al., 2012) and interacts with transforming growth factor-β2 (TGF-β2) (Bilandzic and Stenvers, 2011). Incomplete testicular descent was reported in *Tgfb2* –/– mice (Sanford et al., 1997) and Leydig cell dysfunction noted in *Tgfbr3* –/– mice, but testicular descent could not be assessed in the latter strain because offspring rarely survive past birth (Sarraj et al., 2010).

In a larger GWAS, isolated (nonsyndromic) cryptorchidism was not associated with any genome-wide significant locus that could be replicated in an unrelated case-control cohort, although SNPs within or near *TGFBR3* were again identified as suggestive (Barthold et al., 2015a,b). These results are in marked contrast to hypospadias and TGCT, which are also considered polygenic, but for which multiple associations have been confirmed using GWAS methodology (Geller et al., 2014; Kanetsky et al., 2009; Litchfield et al., 2018; Wang et al., 2017). Pathway analysis of suggestive ($P < 0.001$) cryptorchidism-associated intragenic SNPs identified enrichment in cytoskeleton-, neural- and AR-related pathways, similar to results of genomic analyses of a rat strain with inherited cryptorchidism (Barthold et al., 2008, 2016a). A comparison of suggestive intragenic GWAS SNPs associated with cryptorchidism with or without TGCT identified *RBFOX* and other neurodevelopmental genes as candidates for further study (Wang et al., 2018a). Future validation of RBFOX paralogs as causal alleles would link human and animal models of cryptorchidism because RBFOX proteins regulate splicing of *CALCA*, which encodes CGRP.

Similarly, studies of animal models of inherited cryptorchidism, including swine, dogs, and rats suggest that the genetic etiology is uniformly complex (Barthold et al., 2016a; Rothschild et al., 1988; Sevillano et al., 2015; Zhao et al., 2014;). At least one-half of testes in the LE/orl rat strain reside in the superficial inguinal pouch (SIP); genetic and genomic studies of this strain suggest polygenic inheritance associated with reduced fetal testosterone production and functional variants in genes encoding AR-interacting proteins (Barthold et al., 2008, 2013, 2014, 2016a).

In summary, **studies of clinical and animal models of cryptorchidism suggest that genetic susceptibility is complex, but that specific causative alleles, other than rare variants in *INSL3, RXFP2*, or *NR5A1*, are mostly unknown at this time.** Failure to identify genetic loci associated with human cryptorchidism is likely related to confounding environmental risk factors and to limitations associated with the reported methodology, particularly insufficient sample size, geographic variability, and phenotypic variability.

Environmental Risk Factors

Population-based studies suggest that the maternal environment may contribute to the risk for cryptorchidism, but it remains unclear if risk is related to maternal exposures, characteristics, or lifestyle. The data available for maternal smoking suggest a mild to moderate increased risk for cryptorchidism in offspring, and a possible increased risk for germ cell abnormalities as compared with cryptorchid boys of maternal nonsmokers (Duarte et al., 2017; Hakonsen et al., 2014; Kjersgaard et al., 2018; Virtanen et al., 2012b; Zhang et al., 2015). Maternal alcohol consumption or binge drinking was associated with cryptorchidism in some studies but not in others (Damgaard et al., 2007; Jensen et al., 2007; Kjersgaard et al., 2018; Mongraw-Chaffin et al., 2008; Strandberg-Larsen et al., 2009; Thorup et al., 2006; Zhang et al., 2015). Several series suggest increased risk with maternal use of acetaminophen or more than one analgesic in midpregnancy or earlier (Jensen et al., 2010a, 2010b; Kristensen et al., 2011; Snijder et al., 2012) and are supported by data suggesting that analgesics can alter hormone production by the human fetal testis in culture (Mazaud-Guittot et al., 2013). However, possibly in part because of variations in type, timing, and degree of fetal exposure, recent meta-analyses concluded that the evidence for association of analgesic use with cryptorchidism in offspring is weak (Gurney et al., 2017a, 2017b; Hurtado-Gonzalez and Mitchell, 2017). Parental occupation is not consistently associated with cryptorchidism in offspring, although some data suggest increased risk in horticulture-related professions (Andersen et al., 2008; Gabel et al., 2011; Jorgensen et al., 2013, 2014; Morales-Suarez-Varela et al., 2011; Pierik et al., 2004;Weidner et al., 1998) or in areas of higher pesticide use (Garcia et al., 2017). In addition, a single study identified reduced breastfeeding and increased use of soy formula as variables associated with first diagnosis of cryptorchidism at an older age (Barthold et al., 2012).

TDS (testicular dysgenesis syndrome) refers to a constellation of reproductive abnormalities including cryptorchidism, hypospadias, infertility, and TGCT, purportedly resulting from impaired testicular function in utero (Sharpe et al., 2008; Skakkebaek 2016). The proposed etiology is a deficiency in fetal androgen production resulting from exposure to EDCs. The concern for a link between EDCs and cryptorchidism arose because of a reported increased risk for cryptorchidism after maternal exposure to diethylstilbestrol (DES) (Gill et al., 1979). In a large cohort study of 1197 men previously exposed to DES and 1038 unexposed men, the RR (risk ratio) of cryptorchidism was 1.9 (95% confidence interval [CI], 1.1 to 3.4) overall. When data were subdivided based on gestational age less than 11 weeks and exposure greater than or equal to 5 g, the RRs were 2.9 (95% CI, 1.6 to 5.2) and 3.2 (95% CI, 1.7 to 6.0), showing that early and significant exposure present the clearest risks (Palmer et al., 2009).

In recent years, concern has increased that EDC exposure is linked to multiple health issues, with the strongest support for association with neurodevelopmental, metabolic, and reproductive disorders, including cryptorchidism (Barthold et al., 2016b; Bonde et al., 2016; Hauser et al., 2015; Lymperi and Giwercman, 2018; Trasande et al., 2016; Virtanen and Adamsson, 2012; Virtanen et al., 2012a). Animal models suggest a relationship between prenatal exposure to antiandrogenic EDCs and risk for cryptorchidism and other reproductive end points, although levels of exposure are much higher than applicable clinically (Rider et al., 2009); concerns exist about the applicability of EDC animal models to humans (Habert et al., 2014); and species-specific, differential sensitivity to EDCs exists. Human testes appear insensitive to inhibition of steroidogenesis by phthalates or DES, but more sensitive to the inhibitory effects of bisphenol A (Heger et al., 2012; Lambrot et al., 2009; Mitchell et al., 2012; N'Tumba-Byn et al., 2012). Additionally, measured levels of anti-androgenic and/or estrogenic EDCs in placenta, breast milk, or cord blood, including pesticides, polychlorinated biphenyls (PCBs), dioxins, perfluorinated compounds, flame retardants (PBDEs), and organotin were not consistently higher in association with affected pregnancies (Cook et al., 2011; Damgaard et al., 2006; Fenichel et al., 2012; Main et al., 2007; Rantakokko et al., 2013; Trabert et al., 2012; Vesterholm Jensen et al., 2014; Virtanen and Adamsson, 2012). Consistent with data showing lack of inhibition of human fetal testicular steroidogenesis by phthalates, levels of individual phthalate metabolites did not show consistent correlation with occurrence of cryptorchidism or hormone levels in affected boys (Main et al., 2006a). Nevertheless, several recent studies suggest possible associations between levels of flame retardant chemicals in maternal hair (Goodyer et al., 2017), bisphenol A in placenta (Fernandez et al., 2016), and organic pollutants in adipose tissue (Koskenniemi et al., 2015), with the occurrence of clinical cryptorchidism. In animal models, recent data suggest that mixtures of antiandrogenic chemicals with different mechanisms of action can cumulatively inhibit fetal reproductive development at low levels of exposure (Conley et al., 2018; Howdeshell et al., 2017), findings that may have more relevance for human populations.

Indirect end points indicative of potential fetal exposure to EDCs include anogenital distance (AGD), a measure of prenatal androgen exposure first described in animal models, and placental weight, a measure of placental function that is associated with intrauterine growth restriction, and may correlate with hCG production during a critical window of testicular descent. Both AGD and placental weight may reflect genetic and/or environmental influences. AGD, perineal length from the posterior margin of the scrotum to the anal verge, is sexually dimorphic and correlated with newborn body weight (Sathyanarayana et al., 2010; Thankamony et al., 2016). Reduced AGD has been correlated with cryptorchidism, hypospadias, AR CAG repeat length, phthalate exposure, maternal analgesic use, reduced duration of breastfeeding, and variants in genes linked to reproductive anomalies, including *ESR1* (Dean and Sharpe, 2013; Eisenberg et al., 2013; Jain and Singal, 2013; Lind et al., 2017; Ortega-Garcia et al., 2016; Sathyanarayana et al., 2012; Thankamony et al., 2014). Placental weight is reportedly reduced in boys with cryptorchidism (Arendt et al., 2016; Ghazarian et al., 2018) and a higher risk for early gestational preeclampsia was linked to possible placental dysfunction in a large population study (Arendt et al., 2018). These observations are in keeping with the strong association between intrauterine growth restriction and cryptorchidism. However, the maternal biomarkers of placental function, hCG and alpha-fetoprotein, were not strongly or consistently associated with cryptorchidism in other studies (Boyd et al., 2006; Chedane et al., 2014; Schneuer et al., 2016a).

Further studies are needed to assess the relationship between environmental exposures and cryptorchidism susceptibility because a causal role for single chemicals or classes of EDCs may be difficult to demonstrate in view of the apparent heterogeneity of disease susceptibility, and the wide variety of EDCs to which humans are exposed may allow for synergistic effects that are difficult to measure (Toppari et al., 2016). **At present, epidemiologic data suggest potential associations with exposure to pesticides, flame retardants, bisphenol A (BPA), or organic pollutants in selected populations and raise the possibility that the cumulative effects of mixtures of multiple anti-androgenic and estrogenic chemicals may increase the risk for cryptorchidism in susceptible individuals.**

Hormonal Defects

Because testicular hormones are required for testicular descent, defective hormone production and/or action may contribute to the pathogenesis of cryptorchidism. Scant data documenting hormone production during fetal life are available in humans, although a recent report suggests that increased variance in amniotic fluid INSL3 levels exist between 13 and 16 weeks in male fetuses subsequently diagnosed with cryptorchidism or hypospadias (Anand-Ivell et al., 2018). When present, hormonal defects may also be manifest during postnatal activation of the HPG axis (see Fig. 46.1). Prospective studies of varying size and quality are available that report neonatal hormone levels in cryptorchidism, and although some data suggest that the HPG axis is abnormal, results are conflicting, and baseline levels may not directly reflect the status of germ cell development. In the first reported series of cryptorchid and control boys undergoing hormonal evaluation in the first few months of life, serum testosterone was lower in 7 of 17 (41%) persistently cryptorchid boys but comparable to control levels in 4 of 25 boys with spontaneous testicular descent (Gendrel et al., 1978). Subsequent studies have shown reduced testosterone and/or LH levels in some series (Facchinetti et al., 1983; Pierik et al., 2009; Raivio et al., 2003) but not in others (Barthold et al., 2004; De Muinck Keizer-Schrama et al., 1988; Grinspon et al., 2018). In larger series, Suomi et al. (2006) showed geographic differences in serum INHB and follicle-stimulating hormone (FSH) levels but no differences in testosterone levels in cryptorchid infants from Finland (*n* = 88, 36% spontaneous descent) or Denmark (*n* = 34, 68% spontaneous descent) as compared with 300 and 399 control boys, respectively.

In this series, INHB levels varied geographically, and when compared with respective controls, were lower in Finnish but not Danish cryptorchid boys. INSL3 levels were reduced in cord blood but not in serum obtained at 3 months of age in persistently cryptorchid males, and testosterone levels in cord blood did not differ from controls (Bay et al., 2007, Fenichel et al., 2015). Neonatal studies do, however, suggest that LH:testosterone and LH:INSL3 ratios are increased in boys with cryptorchidism, potentially indicating that subtly reduced Leydig cell function may lead to compensatory upregulation of LH levels (Bay et al., 2007; Suomi et al., 2006). A similar form of compensated Leydig cell function has also been described in adults with reduced semen quality (Jorgensen et al., 2016). Nevertheless, in the largest series to date of 225 boys with congenital cryptorchidism in whom LH, FSH, testosterone, and INHB were measured at 0 to 3 weeks, 2 months, and 6 months of age (*n* ≥57 per time point), hormone levels were not significantly different among unilateral, bilateral, and spontaneously resolving cryptorchid cases, and did not correlate with spermatogenesis (Kollin et al., 2012). In accordance with genetic studies, these varied results suggest significant heterogeneity in infants with cryptorchidism that is in part based on geography.

In older boys, hormonal defects are more difficult to identify because LH, FSH, and testosterone levels fall to low or undetectable levels as the HPG axis becomes quiescent during childhood (Grinspon and Rey, 2010). However, INHB and AMH levels remain easily measurable during childhood (see Fig. 46.1), and these Sertoli cell–specific proteins are sensitive biomarkers of testicular activity during prepuberty (Edelsztein et al., 2016; Grinspon et al., 2012a). Although levels of serum AMH and INHB in older boys also show variability, increasing evidence suggests that Sertoli cell dysfunction is present, particularly in bilateral cryptorchidism (reviewed in Grinspon et al., 2018). In a randomly generated subset of cases from an extensive database, Grinspon et al. found that AMH levels were reduced in 17% of cryptorchid boys, including 22% of bilateral (*n* = 186) and 8% of unilateral (*n* = 124) cases younger than 9 years of age (Grinspon et al., 2018). Gonadotropin levels were either normal or (rarely) elevated in these patients: of nonanorchid boys, FSH was mildly increased (>97th percentile for age) in 4 (3%) unilateral and 7 (4%) bilateral cases, and LH was mildly increased in 9 (7%) unilateral and 10 (5%) bilateral cases. In contrast, Thorup and colleagues (2015) reported that FSH was increased in 25% and 18%, while INHB was reduced in 13% and 16% of bilaterally (*n* = 69) and unilaterally (*n* = 50) cryptorchid infant boys. However, these studies used reference standards rather than control subjects for comparison. In a cohort of similar age, both AMH and INHB were also significantly reduced in cryptorchid as compared with control boys, and more severely in bilateral cases (Hamdi et al., 2017). Yet in another series of 62 older boys (mean age 7.7 years), no differences were identified in inhibin B levels, or in LH, FSH, or testosterone levels before or after hCG stimulation (Christiansen et al., 2002). These varying results may be related to differences in populations or to other confounding factors, such as maternal smoking, which was associated with reduced INHB in cryptorchid offspring (Hildorf et al., 2019). Reduced or unexpectedly low levels of prepubertal serum gonadotropins is some boys has led investigators to posit that an absolute, transient, or relative gonadotropin deficiency may be a cause of cryptorchidism and germ cell loss (Cortes et al., 2016a,b; Hamdi et al., 2017; Verkauskas and Hadziselimovic, 2016; Verkauskas et al., 2016). However, these data are difficult to interpret, the HPG axis is inactive in childhood, and gonadotropin levels may be normal, even in cases of anorchia (Grinspon et al., 2012b).

In additional studies, hormonal changes after orchidopexy suggested a potential beneficial effect of surgery. In a longitudinal study of 27 boys (mean age 4.8 years, 25 with unilateral cryptorchidism) undergoing orchidopexy, an increase in serum INHB was identified in 81% of cases 6 months postoperatively (Irkilata et al., 2004). Thorup et al. reported that INHB levels were more commonly abnormal in uncorrected (23%) as compared with corrected (11%) cryptorchidism cases (Hildorf et al., 2019; Thorup et al., 2015b). INHB levels increased postoperatively in 13% of bilateral and 32% of unilateral cases followed longitudinally by this group in other studies but normalized in less than one-half of cases and did not closely correlate with testicular histology (Thorup et al., 2012, 2015a). Elevated FSH levels, present in 25% of the bilaterally cryptorchid cases, also normalized postoperatively in 82% of these cases. However, changes in FSH and INHB levels over time in these studies are difficult to interpret, because considerable intra-individual fluctuation exists, even in normal males, in the first 2 years of life (Andersson et al., 1998).

Various hormonal defects in nonsyndromic cryptorchidism have been proposed. These include (1) a gonadal defect that is either primary or caused by the adverse effects of testicular position on Sertoli cell function (Grinspon et al., 2018), with or without hypergonadotropic hypogonadism (Cortes et al., 2016b), or (2) isolated or transient HH characterized by unexpectedly normal FSH and LH levels despite low INHB (Cortes et al., 2016b) and association of poor spermatogonial differentiation with low LH levels (Verkauskas and Hadziselimovic, 2016; Verkauskas et al., 2016) or reduced Leydig cell response to hCG (Zivkovic et al., 2007). Isolated HH as a cause of nonsyndromic cryptorchidism and rationale for adjuvant hormonal therapy remain areas of controversy (Biers and Malone, 2010; Chua et al., 2014; Rosch and Schroder, 2016; Verkauskas and Hadziselimovic, 2016; Verkauskas et al., 2016), but direct measurements of hormone levels during mini-puberty (as noted earlier) tend to suggest *increased* gonadotropin drive. Complex interplay between genetic and/or environmental factors at multiple levels of the HPG axis, with adverse effects on testicular descent, hormonal function, and testicular development may be difficult to tease out (Barthold and Ivell, 2018; Barthold et al., 2018). **Whatever the cause, these studies suggest that some cryptorchid boys have abnormalities of the HPG axis, with stronger support for primary gonadal (Sertoli and/or Leydig cell) defects and less for central hypogonadism in nonsyndromic cases.** Inconsistent findings among studies are likely based on timing and type of assays, sample size and heterogeneity based on age, severity, genetic background and/or other interindividual differences. No hormonal studies to date have been shown to precisely predict germ cell numbers or subfertility in cases of cryptorchidism. Because multiple genetic and environmental factors likely contribute to cryptorchidism, identification of risk factors for HPG axis dysfunction will require further research.

Syndromic Cryptorchidism

Undescended testes are frequently present in association with diseases characterized by a major reduction in androgen production and/or action, such as androgen biosynthetic defects, androgen insensitivity, Leydig cell agenesis, and gonadotropin deficiency disorders (Barthold et al., 2000; Foresta et al., 2008). Conditions associated with generalized failure of masculinization are considered disorders of sexual differentiation (DSD) and are not reviewed here (see Chapter 48). Persistent müllerian duct syndrome, a DSD resulting from defective AMH signaling, is also associated with cryptorchidism or transverse testicular ectopia (Josso et al., 2006; Picard et al., 2017). Gubernacular defects that are observed in these patients may be caused by hindrance of descent by retained müllerian ducts (Barteczko and Jacob, 2000) and/or via loss of direct proliferative effects of AMH on the gubernaculum (Hutson and Lopez-Marambio, 2017; Kubota et al., 2002). The frequency of Klinefelter syndrome (47,XXY) is less than 2% in large series of primarily nonsyndromic cryptorchidism but is more frequent when other anomalies, particularly hypospadias, are present (Barthold et al., 2015a; Ferlin et al., 2008; Moreno-Garcia and Miranda, 2002; Sasagawa et al., 1996). More than one-half of prepubertal patients with Klinefelter syndrome have cryptorchidism (Pacenza et al., 2012). Other genomic rearrangements and trisomies, including Down syndrome (trisomy 21), are associated with cryptorchidism (Hadziselimovic, 1983).

Certain congenital anomalies are associated with increased risk for cryptorchidism, many related to musculoskeletal, CNS, or abdominal wall/gastrointestinal defects, and some may occur together. These include all cases of classic prune belly (triad or Eagle-Barrett) syndrome; 53% to 80% of Spigelian hernia (Bilici et al., 2012; Balsara et al., 2014; Durham and Ricketts, 2006; Jones and Hutson, 2015); 25% to 54% of cerebral palsy (CP; Barthold and Ivell, 2018; Barthold et al., 2018; Cortada and Kousseff, 1984; Rundle et al., 1982); 38% of arthrogryposis (Fallat et al., 1991); 15% of myelomeningocele (Ferrara et al., 1998); 16% to 33% of omphalocele; 5% to 25% of gastroschisis (Corona-Rivera et al., 2016; Kaplan et al., 1986; Koivusalo et al., 1998; Yardley et al., 2012); 19% of imperforate anus (Cortes et al., 1995b); 12% to 17% of posterior urethral valve (Heikkila et al., 2008; Krueger et al., 1980; Wong et al., 2016); 7% to 30% of congenital diaphragmatic hernia (Azarow et al., 2015); and 6% of umbilical hernia (Kaplan et al., 1986) patients. Multisystem congenital anomalies are often associated with omphalocele (80%), prune belly syndrome (45%), and CP (19%), suggesting syndromic etiologies (Barthold and Ivell, 2018; Barthold et al., 2018; Koivusalo et al., 1998; Loder et al., 1992). Depue also reported a significant association of cryptorchidism with CNS dysfunction, particularly CP (relative risk [RR] = 34), low IQ (RR = 2.7), and hypotonia (RR = 3.6) (Depue 1988). In more recent population-based studies, additional associations with autism and other developmental abnormalities were reported (Chen et al., 2018;, Rotem et al., 2018; Rzhetsky et al., 2014; Schieve and Shapira, 2018; Schneuer et al., 2017). Cortes et al. (1998) reported associations between renal and T10–S5 spinal anomalies, considered caudal developmental field defects, and cryptorchidism, with the affected testis on the same side as the renal anomaly in 90% of cases. Similarly, cryptorchidism was ipsilateral to the side affected by CDH in all cases (Azarow et al., 2015). In addition, syndromic cryptorchidism, especially in association with CP or CNS malformations, is more commonly bilateral (Barthold and Ivell, 2018; Barthold et al., 2018; Cendron et al., 1993; Cortes et al., 1995b). These data support common origins of cryptorchidism and anomalies of urogenital ridge, abdominal wall, lumbosacral spine, and CNS development.

The occurrence of cryptorchidism with other nongenital anomalies may complicate and/or alter the timing of treatment. For example, Spigelian hernia may be difficult to diagnose, and associated absence of the gubernaculum and inguinal canal may complicate orchidopexy (Balsara et al., 2014; Bilici et al., 2012). Spontaneous testicular descent is reported in 50% to 55% of gastroschisis cases (Hill and Durham, 2011; Yardley et al., 2012), suggesting that observation is warranted.

Diagnosis

Examination

To best determine testicular position, boys should be examined in the supine and, if possible, upright cross-legged and standing positions. Abduction of the thighs contributes to inhibition of the cremasteric reflex, which is elevation of the testis that is elicited by scratching the inner thigh. The examination should include documentation of testicular palpability, position, mobility, size, and possible associated findings such as hernia, hydrocele, penile size, and urethral meatus position. Patient distraction, a warm room and hands, use of liquid soap or lubricant on the examiner's hands, and repeated examinations also help localize the testis and limit cremaster muscle activity and resultant difficulty in determining testicular position. Sustained gentle traction on the cord can help inhibit the cremaster reflex and allow a retractile testis to remain at least temporarily in stable scrotal position. Scrotal asymmetry can be a useful clinical sign as it is commonly present in boys with unilateral cryptorchidism (Fig. 46.4) (Snodgrass et al., 2011).

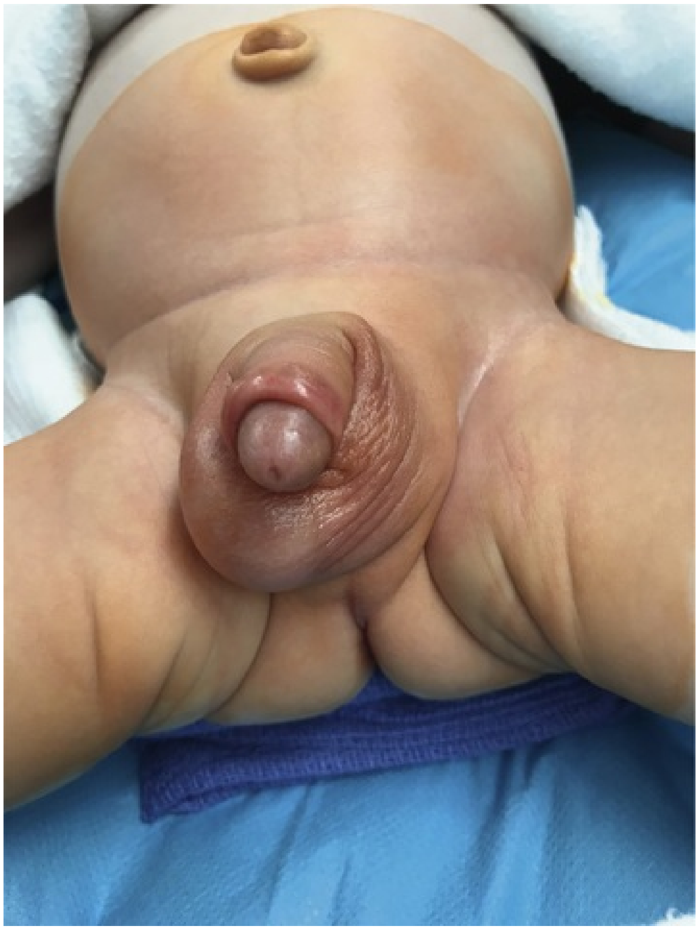

FIG. 46.4 Scrotal asymmetry in a boy with unilateral left cryptorchidism.

In large clinical series, the majority (75% to 80%) of undescended testes are palpable and 60% to 70% are unilateral; involvement of the right side is more common overall but less frequent in series of nonpalpable testes (Cendron et al., 1993; Cortes et al., 2001; Giannopoulos et al., 2001; Hadziselimovic 1983). Position of undescended testes varies markedly with the population studied, which may in part be a result of different classification techniques. In a meta-analysis of surgical patients, testes were abdominal in 34%, near the internal ring (“peeping”) in 12%, canalicular in 27%, and beyond the external ring in 27% (Docimo, 1995), and in large single-institution series, testes were abdominal in 3% to 10% of total cases, were canalicular in 16% to 27% of cases, and the majority were distal to the external ring (Cendron et al., 1993; Hadziselimovic 1983; Kraft et al., 2011; Moul and Belman, 1988). In a multi-institutional review of almost 40,000 European cryptorchid boys, 8% of testes were abdominal, 63% were canalicular, 24% were prescrotal, and 11% were SIP or ectopic. Moul and Belman classified all subinguinal testes with a lateral gubernacular attachment as ectopic (66% of their total cases).

Associated genital findings may warrant additional diagnostic studies that are best completed in the neonatal period. If neither testis is palpable, particularly if penile development is abnormal, karyotype and hormonal analyses are performed urgently to rule out congenital adrenal hyperplasia and obviate the potential adverse effects of undiagnosed salt wasting. Routine circumcision if desired should be delayed until evaluation confirms a genetically normal male. Hypospadias is associated with cryptorchidism in 12% to 24% of cases (Cendron et al., 1993; Cox et al., 2008; Moreno-Garcia and Miranda, 2002). If proximal hypospadias is present, chromosomal analysis is warranted as the frequency of abnormalities is high (32% to 47%) (Cox et al., 2008; Sekaran et al., 2013). Micropenis was reported in 46% of boys with anorchia caused by bilateral vanishing testes (Zenaty et al., 2006) (also called *testicular regression syndrome*), and small penile size in association with cryptorchidism is also observed in cases of hypogonadotropic hypogonadism. In these cases, measurement of **testosterone, LH, and FSH levels in the first few months of life during the window of opportunity afforded by the physiologic activation of the HPG axis can facilitate early identification of hormone deficiency or anorchia** (Grumbach, 2005).

Palpable Testes

Undescended testes may be located along the line of normal descent between the abdomen and scrotum or in an ectopic position that is most commonly the SIP (anterior to the rectus abdominus muscle) or, more rarely, in a perirenal, prepubic, femoral, peripenile, perineal, or contralateral scrotal position (Fig. 46.5). Careful examination of these areas is needed to correctly classify a testis as palpable or nonpalpable, a critical step that influences further diagnosis and treatment (Fig. 46.6). Every effort should be made by the examiner to determine the lowest position the testis may attain. Manual downward pressure with one hand along the ipsilateral inguinal canal from the anterior iliac spine to the scrotum and palpation with the opposite hand helps identify the lowest position of a palpable testis.

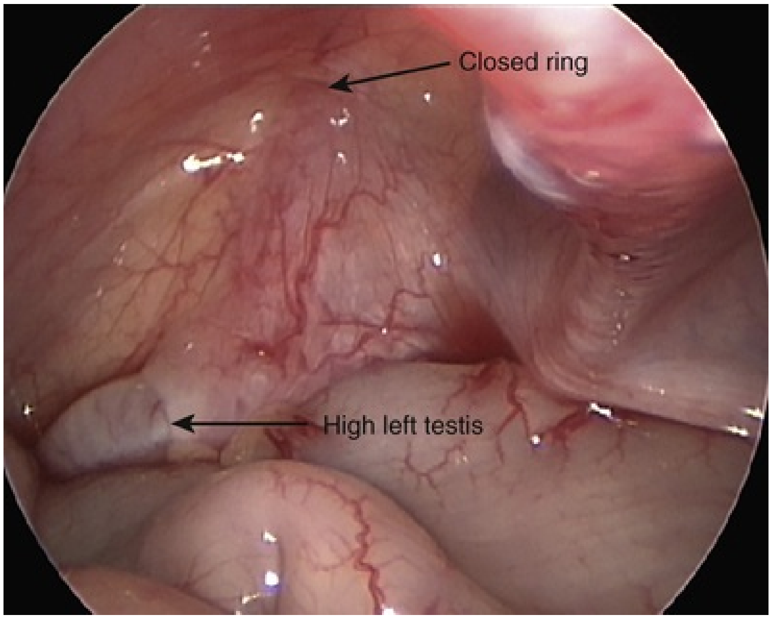
FIG. 46.6 Algorithm for management of the undescended testis. The American Urological Association guideline algorithm for diagnosis and treatment of palpable and nonpalpable testes in patients confirmed to have undescended testis by an experienced examiner. *DSD,* Disorder of sexual differentiation. (From American Urological Association. Evaluation and treatment of cryptorchidism (2014). Available at: http://www.auanet.org/education/guidelines/cryptorchidism.cfm.)

Difficulty in the clinical classification of cryptorchidism when the testis is palpable is related to both documentation of testicular position and differentiation of truly undescended from retractile testes, complicated by the fact that these entities may coexist. The gold standard for diagnosis remains careful examination of a child in several positions and confirmation of incomplete descent of the testis to a dependent scrotal position after induction of anesthesia. Prospective studies of intraobserver and interobserver variation show major differences in documentation of testicular position among examiners (Olsen 1989; Wit et al., 1987). Olsen noted complete agreement between two examiners on scaled measures of testicular position and mobility in only 5 (13.5%, 95% CI, 4.5% to 28.8%) of 37 boys. Cendron et al. (1993) reported that preoperative testicular position correlates poorly with intraoperative findings. Frimberger et al. also demonstrated an inability to consistently predict an absence of an intraabdominal testicle by the scrotal examinations in children with nonpalpable testicles. Of 74 children, 4 were predicted to have nubbins by an experienced surgeon and were found on laparoscopy to have a viable testicle (Frimberger et al., 2015). Variation in observed testicular position preoperatively and postoperatively may influence assessment of prognosis and outcome in boys with cryptorchidism.

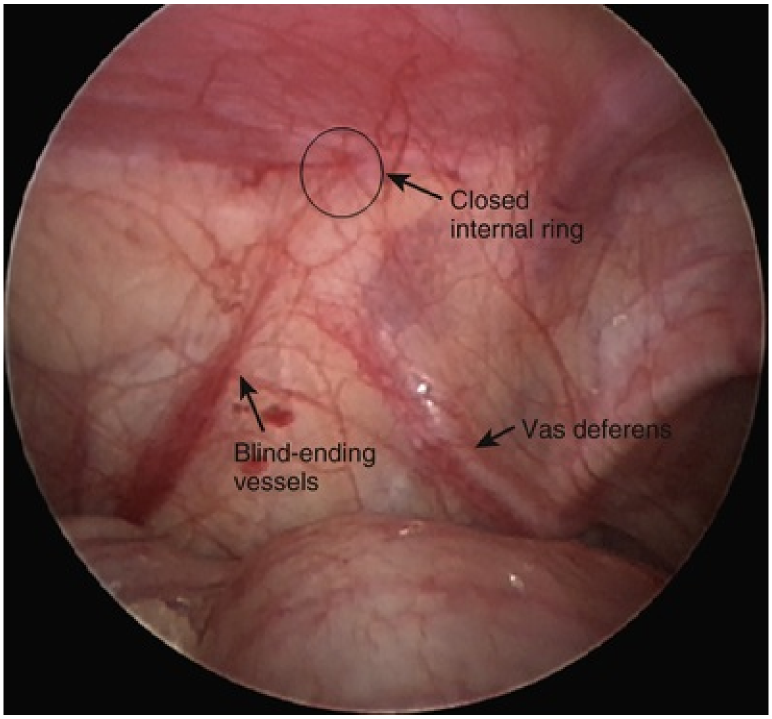
Nonpalpable Testes

When a testis is nonpalpable, possible clinical findings at surgery include (1) abdominal or transinguinal “peeping” location (25% to 50%) (Fig. 46.7), (2) complete atrophy (“vanishing” testis, 15% to 40%) (Fig. 46.8), and (3) extra-abdominal location but nonpalpable because of body habitus, testicular size, and/or limited cooperation of the patient (10% to 30%) (Cendron et al., 1993; Cisek et al., 1998; Kirsch et al., 1998; Patil et al., 2005; Radmayr et al., 2003). If both testes are nonpalpable and not distal to the internal inguinal ring in a genetic male, at least 95% are abdominal, with cases of bilateral vanishing testis occurring rarely (Cendron et al., 1993; Moore et al., 1994). If neither vas nor spermatic artery is found at the time of laparoscopy, laparoscopic or surgical dissection of the perivesical area and retroperitoneum up to the level of the kidney is required to exclude the presence of a testis, as true agenesis is extremely rare. Perirenal or other abdominal testes may be associated with multicystic dysplastic or absent ipsilateral kidneys and/or nonunion of the testis and epididymis (Foley et al., 2005; Kim et al., 2005; Zaccara et al., 2004).



Closed ring
High left testis

FIG. 46.7 High intra-abdominal testis identified on laparoscopic evaluation. Left testis identified high in the abdomen is associated with a closed internal ring.



Closed internal ring
Blind-ending vessels
Vas deferens

FIG. 46.8 Vanishing testis noted on laparoscopic evaluation. Note the blind ending spermatic vessels and vas deferens.

The etiology of vanishing testis is not known but is thought to represent spermatic cord torsion or vascular accident occurring after completion of genital masculinization but before fixation of the testis in the scrotum. Evidence supporting this etiology includes the presence of hemosiderin in remnant testicular “nubbins” excised at surgery (Turek et al., 1994) and reported cases of contralateral postnatal torsion (Gong et al., 1996). An enlarged contralateral testis (Huff et al., 1992) and absence of palpable intrascrotal “appendage” tissue (processus vaginalis, Wolffian structures, or gubernaculum) are highly predictive of a vanishing testis (Mesrobian et al., 2002). In a recent review, contralateral testicular volume of greater than 2 mL was reported to have 72% sensitivity and 100% specificity (Hodhod et al., 2016) in line with prior work (Huff et al., 1992; Koff, 1991). A contralateral testicle cutoff length of 19 to 20 mm has been shown to be accurate in predicting which children will be found to have a solitary testicle (Braga et al., 2014). This information can be useful in preoperative counseling but should not negate further surgical workup. **Diagnosis of a vanishing testis requires documentation of blind-ending spermatic vessels in the abdomen, inguinal canal, or scrotum.**

Hormonal Evaluation

Endocrine evaluation in cases of suspected bilateral vanishing testes (anorchia) shows elevated basal serum gonadotropin levels and no response to hCG stimulation; however, gonadotropins may be unexpectedly low in mid-childhood (Grinspon et al., 2012b; Lee, 2000; Lustig et al., 1987). Because hCG stimulation testing is not well standardized and has the potential for side effects and inaccuracy, it is no longer the procedure of choice for documentation of anorchia (Kolon et al., 2014). In most cases, laparoscopic or surgical abdominal exploration is performed, although hormone testing can also be useful and may be sufficient for the diagnosis of anorchia, particularly when taking advantage of the window of opportunity provided by mini-puberty. In the absence of testicular tissue, FSH and LH are higher than normal in early infancy and, at any point in childhood, AMH and INHB levels are useful adjuncts in the diagnosis of anorchia (Brauner et al., 2011; Grinspon et al., 2012b; Grumbach 2005; Lee et al., 2003; Thorup et al., 2011b). Very low or undetectable AMH and INHB, together with high levels of gonadotropins (LH >5 IU/L and FSH >2 IU/L in boys 0.5 to 6 years of age or LH or FSH >5 IU/L in boys 6 to 11 years of age) are diagnostic for anorchia. Gonadotropin levels may be normal in cases of anorchia during childhood (Grinspon et al., 2012b), and in these cases laparoscopy is required to confirm the diagnosis.

Imaging

Although many children have imaging done before referral to a surgical specialist, inguinoscrotal ultrasonography and magnetic resonance imaging (MRI) are not usually helpful and are not recommended in the evaluation and management of a nonpalpable testis (Elder 2002; Kolon et al., 2014; Tasian et al., 2011). Overall, the sensitivity and specificity of ultrasonography in localizing the nonpalpable testis is 45% and 78%, respectively (Tasian et al., 2011). In a recent meta-analysis, the sensitivity and specificity of MRI in identifying cryptorchid testes was 65% and 100%, respectively, and was higher for inguinal than for abdominal testes (Krishnaswami et al., 2013). No imaging modality is reliable for diagnosing vanishing testes. Some authors advocate very selective use of imaging if recommended by the managing surgical specialist after referral; in this situation, the sensitivity of ultrasonography in identifying inguinal testes is reported to be as high as 95% to 97%, and abdominal testes are also seen in some cases (Cain et al., 1996; Nijs et al., 2007), but examination under anesthesia is likely to provide the same information (Tasian et al., 2011). Similarly, MRI can be useful in some cases to identify nonpalpable abdominal testes, but its accuracy is variable, the procedure requires sedation in younger children, and it is unlikely to change the management approach (Hartigan and Tasian, 2014; Shepard and Kraft, 2017; Siemer et al., 2000; Yeung et al., 1999). The superior accuracy of magnetic resonance angiography (MRA) in localizing and differentiating viable from vanished testes (96% of 23 nonpalpable testes in 21 boys, mean age 2.5 years) has not been replicated in a recent study of younger boys (57% of 29 testes in 26 boys, mean age 13 months) (Desireddi et al., 2008; Yeung et al., 1999). One indication for MRI may be identification of an ectopic abdominal testis not localized by laparoscopy. Despite the consensus that imaging is not indicated, it is still very commonly performed. In a large review of a Canadian data warehouse, it was found that up to 50% of referred patients had ultrasound examinations, which ultimately delayed surgical intervention by 3 months and was only accurate 54% of the time (Kanaroglou et al., 2015). **Imaging is not indicated for diagnosis of the nonpalpable testis, as it has limited accuracy and does not obviate the need for definitive surgical intervention.**

Diagnostic Laparoscopy

Diagnostic laparoscopy, followed by laparoscopic orchidopexy if an abdominal testis is present, has become the preferred approach to the nonpalpable testis for many clinicians. Laparoscopy is preceded by an examination under anesthesia, which may be a useful adjunct that helps define the appropriate course of action. Although laparoscopy does not always provide a direct diagnosis, in many cases it either provides visualization of the testis or guidance for the surgeon's next steps. Important laparoscopic observations include the size and position of the spermatic vessels and vas; testicular size, quality and position if visible; and patency of the internal inguinal ring. The combination of a closed internal ring and a blind-ending spermatic artery and vas confirms an abdominal vanishing testis (see Fig. 46.8), and a hernia is frequently but not always associated with a viable abdominal or distal testis (Elder, 1994; Moore et al., 1994). An atretic spermatic cord coursing through a closed inguinal ring is suggestive of a distal vanishing testis, but this finding may be subjective, and, conversely, normal appearing vessels may be associated with both viable and vanishing testes (Zaccara et al., 2004). Moreover, the laparoscopic view may suggest abdominal blind ending vessels despite a testis being present distally or in an ectopic abdominal position (Ellsworth and Cheuck, 2009; Kim et al., 2005; Zaccara et al., 2004). Therefore, **if laparoscopy does not unequivocally localize the testis or blind-ending spermatic artery, additional surgical exploration is needed for definitive diagnosis. This may be performed laparoscopically after the placement of additional working ports.**

The need for excision and contralateral scrotal orchidopexy in vanishing testis cases remains controversial. Germ cells and/or tubules are consistently present in 5% to 15% of excised testicular remnants (Bader et al., 2011; Cortes et al., 1995a; De Luna et al., 2003; Moore et al., 1994; Renzulli et al., 2005; Tennenbaum et al., 1994; Turek et al., 1994), but the risk for malignancy is unknown. Rozanski et al. (1996) reported a single case of carcinoma in situ in a testicular remnant. Excision is appropriate when the spermatic vessels traverse the internal inguinal ring, to provide confirmation that no viable (or atrophic) testis is present, as the laparoscopic appearance of the spermatic vessels and processus vaginalis may be deceiving and may not reliably exclude the presence of an inguinal testis (Ellsworth and Cheuck, 2009). Vanishing testes are often in or near the scrotum; therefore, initial scrotal exploration can be considered when a palpable scrotal “nubbin” and contralateral testicular hypertrophy (testicular length ≥ 1.8 cm) are present (Belman and Rushton, 2003; Snodgrass et al., 2007). However, a transscrotal search is time-consuming and unproductive when a vanishing testis is intraabdominal. Moreover, in cases of testicular-epididymal dissociation, a scrotal “nubbin” may actually be the epididymis instead of a vanishing testis; a laparoscopic approach facilitates more accurate diagnosis and subsequent management of such cases (De Luna et al., 2003; Wolffenbuttel et al., 2000). **Laparoscopy is the procedure of choice to confirm or exclude the presence of a viable or remnant abdominal testis, unless a prominent scrotal nubbin is palpable with other clinical signs of monorchism.**

Contralateral fixation of a solitary testis in cases of monorchism is advocated by some but not universally supported. The possibility that prenatal torsion is the etiology of vanishing testis (Gong et al., 1996) does not imply that the contralateral testis is likely to undergo a similar fate after the postnatal period and may not warrant the risk from surgery (Kehoe and Christman, 2017). However, some surgeons empirically recommend contralateral fixation to eliminate the risk for such a devastating complication (Rozanski et al., 1996) and/or because a contralateral bell-clapper deformity (incomplete testicular fixation to the tunica vaginalis) may be present (Al-Zahem and Shun, 2006; Bellinger 1985). However, review of the anatomy of the tunica vaginalis contralateral to vanishing testes suggests that the bell-clapper anomaly is rare and the risk for torsion of the solitary testis in these cases is minimal (Martin and Rushton, 2014).

Associated Pathology

Testicular Maldevelopment

Many observational studies of the histologic development of prepubertal normal and cryptorchid testes have been published. Over 40 years ago, Mancini et al. (1965) systematically measured germ cell counts and reported arrested development of spermatogonia with progressive loss in cryptorchid testes. Additional histologic studies of prepubertal cryptorchid testes have generally shown decreased germ cell numbers beginning after infancy, and failure to increase with age in cryptorchid, and to a lesser degree, contralateral scrotal testes (Cortes et al., 2001; Gracia et al., 1995; Hadziselimovic et al., 1986; Hedlinger 1982; Huff et al., 2001a; Kraft et al., 2011; Kollin et al., 2012; McAleer et al., 1995; Schindler et al., 1987; Tasian et al., 2009; Thorup et al., 2012, 2013). When reported, the frequency of abnormal histology in affected testes varied between studies, ranging from 38% to 98%. Some patient populations excluded individuals who responded to hormonal therapy and therefore did not undergo surgery with biopsy. Other variables include differing histologic methods and/or use of age-corrected normative values. A recent systematic review and meta-analysis defined precise age-dependent reference values from studies of normal boys (Masliukaite et al., 2016). These data show that the average (95% CI) number of spermatogonia per tubule (S/T) is 2.5 (2.3 to 3.0) at birth, 2.2 (1.8 to 2.6) at 1 year of age, 1.2 (1.0 to 1.4) at 2 to 3 years of age, 2.0 (1.7 to 2.3) at 4 years of age, and 2.5 (2.1 to 2.9) at 5 years of age, where it remains steady until early puberty (11 years of age). The drop in mean S/T values at 2 to 3 years of age to levels that are one-half of those seen at earlier and later ages would suggest a requirement to report age-specific data. In contrast, data obtained at autopsy from 69 normal boys 0 to 1.9 years of age showed a gradual reduction, with no secondary rise in the number of germ cells per tubule (Kvist et al., 2018). Of note, variability within and between biopsies from single testes has been reported (Hedlinger 1982; Schindler et al., 1987).

Despite these limitations, the available data provide strong evidence that abnormal germ cell development is often present after early infancy in cryptorchid testes and, to a lesser degree, in their descended partners. The degree of pathology reported was similar in true ectopic, superficial inguinal pouch, abdominal, and ascending testes (Herzog et al., 1992, Hutcheson et al., 2000b; Kollin et al., 2012; Rusnack et al., 2002), although some studies suggest higher severity may be associated with an abdominal location (Gracia et al., 1995; Kollin et al., 2012; Schindler et al., 1987; Tasian et al., 2009). Germ cell depletion was also present in limited samples from patients with myelomeningocele, posterior urethral valves, and prune belly syndrome (Orvis et al., 1988; Patel et al., 2008). Findings are similar in boys with secondary cryptorchidism after hernia repair, suggesting that these may in fact be cases of primary cryptorchidism (Fenig et al., 2001), although the secondary effects of malposition may also contribute to germ cell depletion (Kollin et al., 2012). In other studies, higher germ cell counts were correlated with reduced age-dependent interstitial fibrosis (Suskind et al., 2008), lower age at surgery, and increased likelihood of testicular palpability (Kraft et al., 2011; Tasian et al., 2009). In a series of 723 boys with cryptorchidism (14% bilateral), testicular volume did not predict germ cell count (Noh et al., 2000), but in a subsequent series of 1326 boys with unilateral cryptorchidism from the same institution, testis volume was positively correlated with germ cell counts in both undescended and contralateral descended testes (Kraft et al., 2011).

Detailed studies of peritubular myoid and Sertoli cells in cryptorchidism are limited, but their abnormal development or function may contribute to the observed germ cell abnormalities. The available data suggest disruption of prepubertal Sertoli cell morphology, failure of maturation at puberty, and evidence for reduced number after 4 months of age in cryptorchid testes (Lackgren and Ploen, 1984; Regadera et al., 2001; Rune et al., 1992; Zivkovic et al., 2009a). Reduced expression of type IV collagen, a product of both Sertoli and myoid cells that may function in cell-to-cell communication, was reduced in basement membranes of undescended and contralaterally descended testes (Santamaria et al., 1990). In their prospective, randomized study, Kollin et al. (2007, 2012) reported that Sertoli cell counts were significantly higher in boys who underwent orchidopexy at 9 months of age as compared with 3 years of age. They also noted that Sertoli cell number and testicular volume were significantly correlated at both time points, and remained higher at 4 years of age in the early surgery group, suggesting that a nonscrotal testis position is detrimental, even in infancy. These histologic data are congruent with recent studies showing that average levels of Sertoli cell hormones are reduced, particularly in bilateral cryptorchidism.

Impaired transformation of gonocytes to spermatogonia is reported in cryptorchid testes and may help define fertility potential. The ratio of gonocytes to spermatogonia appears to be normal in cryptorchid testes at about 1.5 months of age, but delays in the disappearance of gonocytes and in the appearance of Ad spermatogonia occur in the undescended as compared with the contralateral descended testis (Hadziselimovic et al., 1986; Huff et al., 2001a). As noted for total germ cell counts, the reported range of cryptorchid testes lacking Ad spermatogonia, 7% to 85%, is wide (Canavese et al., 2009; Thorup et al., 2013; Verkauskas et al., 2019; Zivkovic et al., 2009b) and also shows geographic variation. Reduced Ad spermatogonia number per tubule (Ad/T) can also be found in the contralateral testis of boys with unilateral cryptorchidism (Kraft et al., 2011; Verkauskas et al., 2019) and was also reported in a series of boys with acquired cryptorchidism (Promm et al., 2016), providing further evidence that these are testes that are not truly descended at birth but escape detection until later in childhood. Additionally, the appearance of primary spermatocytes at 4 to 5 years of age is delayed in cryptorchid testes (Huff et al., 1989, 2001a).

Kollin et al. studied testicular growth in undescended and scrotal testes and measured the effect in orchidopexy on testicular size using serial ultrasonography in prospective randomized studies of congenital cryptorchidism (Kollin et al., 2006, 2007, 2012, 2013). They showed that the undescended testis is smaller at birth and grows less well than the scrotal testis, even if spontaneous descent occurs. Postoperative testicular growth was superior in boys who underwent orchidopexy at 9 months of age as compared with those randomized to surgery at 3 years of age. Biopsies at the time of orchidopexy in these patients showed marked reductions in germ cell number and a less prominent reduction in Sertoli cells when orchidopexy was delayed until 3 years of age. In these studies, INHB levels correlated with testicular volume, as reported previously for neonates with normal testes, where INHB levels were interpreted to primarily reflect differences in Sertoli cell number (Main et al., 2006b; Sharpe 2006). **These well-conducted prospective studies suggest that cryptorchidism is associated with primary and secondary effects on testicular development, and that an extrascrotal position may have adverse effects, even in infancy.** Because Sertoli cells provide critical paracrine signaling during the process of spermatogonial differentiation (Manku and Culty, 2015), it is possible that the histologic abnormalities observed in cryptorchid testes are the result of functional defects in Sertoli cells, germ cells, or both.

Anomalies of the Epididymis, Processus Vaginalis, and Gubernaculum

Attachment of the epididymis to the testis may be abnormal in cryptorchid boys (Marshall and Shermeta, 1979), with a reported frequency that varies from 16% to 75% (Gill et al., 1989; Heath et al., 1984; Kraft et al., 2011; Merksz and Tóth, 1987; Mollaeian et al., 1994), in part because identification of this anomaly may be subjective. **Anatomic findings in decreasing order of frequency include partial or complete nonfusion between the caput and/or cauda epididymis and the testis, epididymal elongation and/or looping, and atresia (Fig. 46.9).** The occurrence of epididymal anomalies correlates with both the severity of cryptorchidism and the degree of closure of the processus vaginalis (Barthold and Redman, 1996; Elder 1992). Epididymal anomalies were more common in congenital (37% to 60%) than in acquired (11% to 31%) cryptorchidism (Barthold et al., 2012; van Brakel et al., 2012). Complete epididymal detachment or nonunion between the testis and epididymis/vas is rare and more likely to be associated with abdominal testes (Foley et al., 2005; Karaman et al., 2011; Sharma and Sen, 2013; Wakeman and Warner, 2010) but did not correlate with testicular histology (Kraft et al., 2011). However, the degree to which these anomalies alter sperm transport, if at all, and potentially contribute to subfertility in males with a history of cryptorchidism, remains undefined.

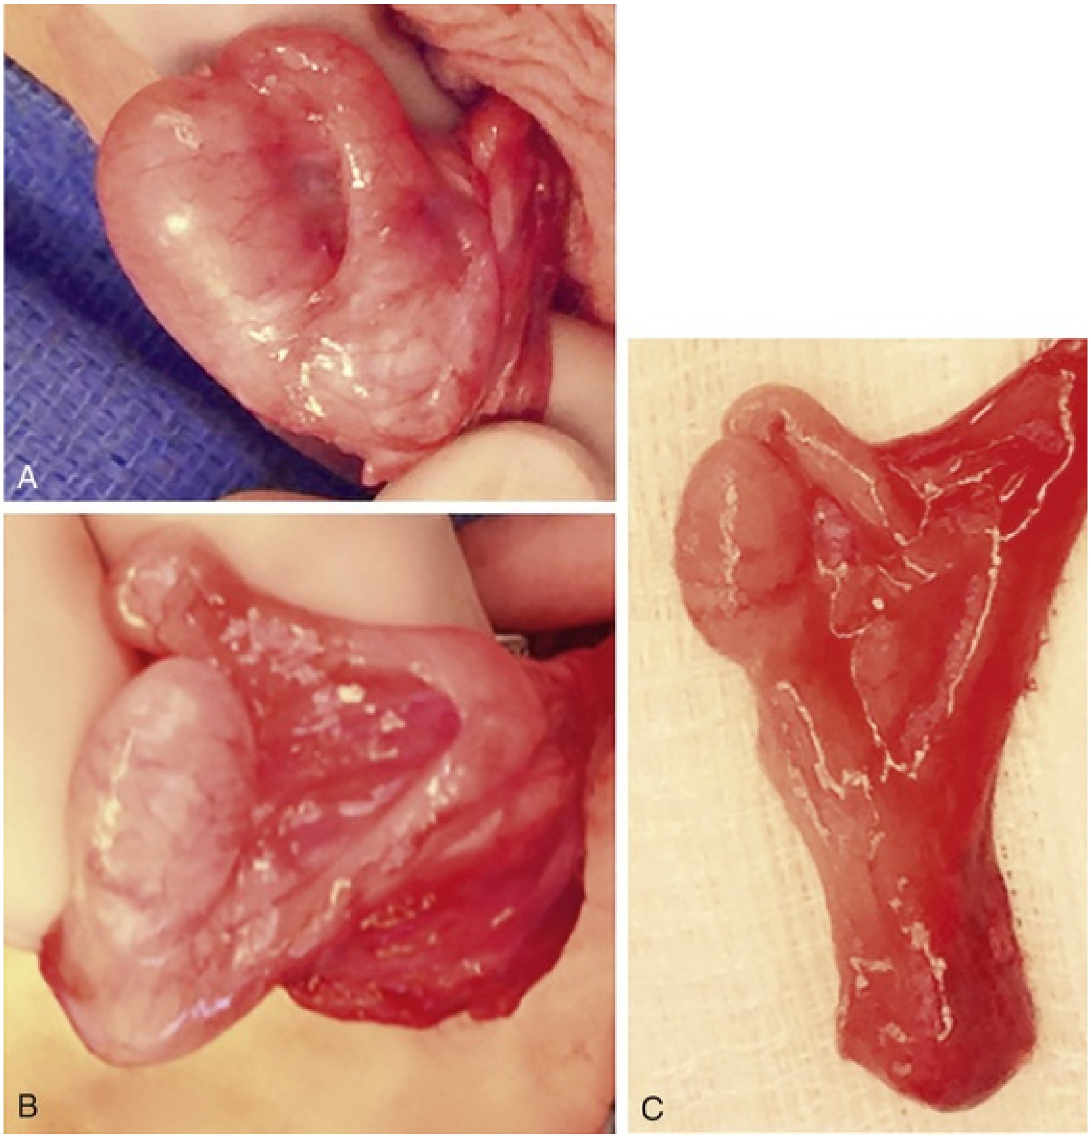


FIG. 46.9 Epididymal anomalies. (A) Normal epididymis. (B) Looped epididymis. (C) Malunion of the tail of the epididymis.

Patency of the processus vaginalis (inguinal hernia) and abnormal attachment of the gubernacular remnant are common in association with cryptorchidism. In their study of 759 patients, Cendron et al. identified a persistently patent processus vaginalis ipsilateral to 87% of unilateral and 71% of bilateral undescended testes. Specific notation of the gubernacular position available from this and another large study indicates aberrant attachment lateral to the scrotum in 66% to 75% of cases (Cendron et al., 1993; Moul and Belman, 1988). The processus is patent in 45% to 50% of boys presenting with ascending testes, possibly related to older patient age and/or reduced severity of cryptorchidism in this group (Barthold and Gozalez, 2003; Barthold et al., 2012; van Brakel et al., 2012). Inguinal hernia is also more common in family members of boys with cryptorchidism (Barthold et al., 2012). **Anomalies of the tunica and processus vaginalis in cryptorchidism predispose to development of testicular torsion or clinical hernia, respectively, in rare cases.** Torsion of an undescended testis can occur at any age (reviewed by Zilberman et al., 2006) and may be confused with an incarcerated inguinal hernia. The risk for torsion is higher in undescended testes than in scrotal testes, and it may be particularly high in children with developmental disorders. Delay in diagnosis is common, and a high index of suspicion is needed to reduce the high risk for testicular loss. A rare but significant concern is the potential risk for torsion with testicular loss in infancy, as boys are observed for spontaneous testicular descent (Singal et al., 2013).

Other Testicular Anomalies Associated With Cryptorchidism

Several rare anomalies of testicular development associated with cryptorchidism, each with 100 to 150 reported cases in the literature, include polyorchidism, splenogonadal fusion, and transverse testicular ectopia. As abdominal cryptorchidism commonly occurs in these cases, laparoscopy is useful in both diagnosis and treatment.

Polyorchidism is the presence of a supernumerary testis that is more commonly unilateral and on the left side, with rare cases of bilateral duplication or triplication reported in a comprehensive meta-analysis of pediatric and adult literature (Bergholz and Wenke, 2009). The cause is unknown, but most authors speculate that this anomaly is related to duplication or division of the genital ridge with or without the Wolffian duct (Danrad et al., 2004). Testes are reported to be scrotal, inguinal, and abdominal in 75%, 20%, and 5% of cases, respectively (Kumar et al., 2008). Affected individuals are frequently asymptomatic, and the polyorchidism is identified at the time of orchidopexy or hernia repair (present in 24% to 30% of cases); other reported associations include a scrotal or inguinal mass, pain (7%), testicular torsion (13% to 15%), persistent müllerian remnants (7% to 9%), and/or testicular tumor (Avargues et al., 2015). Various classification schemes have been proposed, with a recent trend toward categorizing testes based on epididymal and vasal configuration (Bergholz et al., 2007; Khedis et al., 2008; Kumar et al., 2008). Kumar et al. suggest a classification that differentiates between testes that are drained by a vas deferens: *Type A1*, separate epididymis and vas; *Type A2*, separate epididymis; and *Type A3*, shared epididymis and vas, from those with no vasal drainage: *Type B1*, epididymis present, and *Type B2*, no epididymis or vas. This classification can aid in management decisions that should be based not only on the anatomy of the accessory ducts but also the position, size, and attachments of the testis. Observation and periodic self-examination without surgery should be considered for sonographically normal scrotal testes and orchidopexy for testes that are undescended but with intact ductal drainage (Bergholz et al., 2007; Khedis et al., 2008; Spranger et al., 2002). Occasional cases of testicular tumor have been reported in supernumerary testes, but it is unclear if this is a risk related to polyorchidism per se or to associated cryptorchidism or persistent müllerian duct syndrome (Ghose et al., 2007; Spranger et al., 2002). Testicular torsion may also occur (Arlen et al., 2014).

Splenogonadal fusion is a defect characterized by continuous or discontinuous fibrous union between splenic tissue and the gonad, a condition much more commonly recognized in males (Khairat and Ismail, 2005) (Fig. 46.10). In the continuous form (55%), a cord connects the testis to the spleen; in the discontinuous form, the splenic tissue is attached to the gonad and not continuous with the main body of the spleen (Ferron and Arce, 2013). Approximately 30% of affected individuals have cryptorchidism, with the majority of cases abdominal and bilateral (59%), and 65% and 26% involving the left and right sides, respectively (Cortes et al., 1996). The continuous form of splenogonadal fusion is more commonly syndromic and associated with limb defects, micrognathia, microglossia, anal atresia, and pulmonary hypoplasia (Celik et al., 2016; McPherson et al., 2003) and less commonly with cardiac defects, cleft palate, imperforate anus, and myelomeningocele (Lin et al., 2010). The discontinuous form can present as a testicular mass, with distinctive ultrasound findings that include a somewhat hyperechoic mass (relative to testis) that contains multiple hypoechoic nodules and obvious vascularity (Ferron and Arce, 2013). The pathogenesis of splenogonadal fusion is unknown, but based on the constellation of defects observed is hypothesized to represent a developmental field defect with aberrant migration of spleen cells occurring at 5 to 8 weeks. Most cases present incidentally at the time of orchidopexy or inguinal hernia repair, or with scrotal swelling related to illness-associated reactive changes within the splenic tissue. Testicular malignancy is reported rarely in association with cryptorchidism and not likely related to the splenic anomaly. Treatment should focus on recognition of the defect at the time of orchidopexy and avoidance of unnecessary orchiectomy.

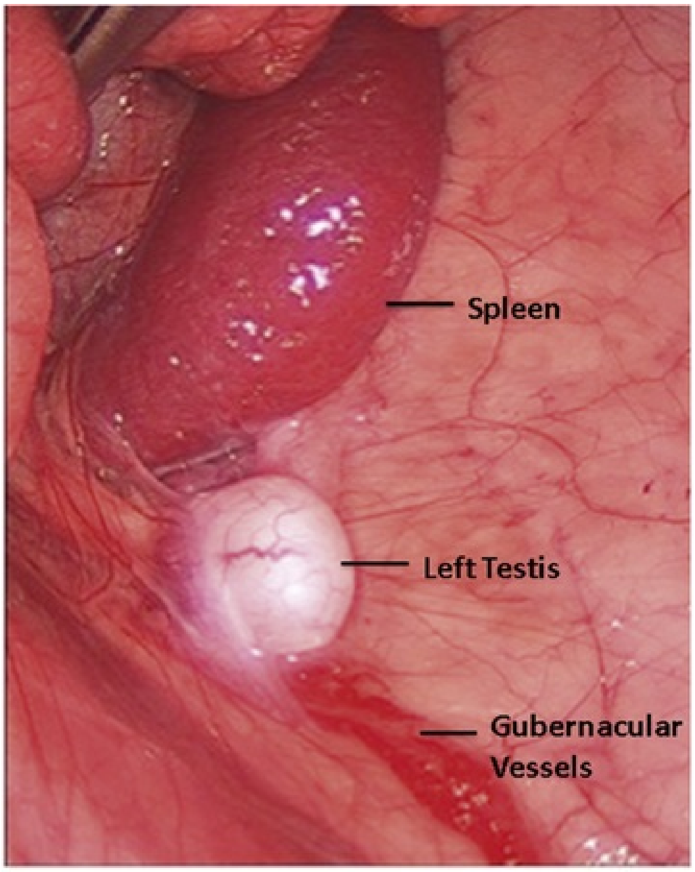

FIG. 46.10 Splenogonadal fusion. A case of continuous splenogonadal fusion in a boy with a left nonpalpable testis with fusion to the spleen as identified by laparoscopy.

Transverse testicular ectopia (TTE) may occur as an isolated anomaly in otherwise normal males with cryptorchidism or vanishing testes, or may be associated with persistent müllerian duct syndrome (PMDS) in 20% to 50% of cases (De Luna et al., 2003; Thambidorai and Khaleed, 2008; Wuerstle et al., 2007). The classic presentation is inguinal hernia with contralateral nonpalpable testis, although both testes may be palpable in the same hemiscrotum. The etiology may be related to mechanical hindrance to descent by fusion of Wolffian duct derivatives (Chacko et al., 2006) or persistent müllerian ducts, or to a primary gubernacular defect. Interestingly, in transgenic *Insl3 –/–* mice, complete loss of the gubernacular attachment, TTE, and/or torsion were observed (Nef and Parada, 1999; Sozubir et al., 2010; Zimmermann et al., 1999). In the largest series of PMDS to date, presentations included bilateral cryptorchidism (59%), unilateral cryptorchidism with contralateral hernia (hernia uteri inguinalis, 19%) or TTE (22%) (Picard et al., 2017). Mutations in *AMH* or its receptor, *AMHR1*, occur in 88% of patients, and infertility is present in at least 80% and testicular malignancy in 33% of adults.

Laparoscopy is a useful adjunct in diagnosis and treatment of TTE (Alamsahebpour et al., 2015). Orchidopexy may be performed using open surgical or laparoscopic techniques, but in cases of vasal fusion, the involved testis is mobilized ipsilaterally and a trans-septal approach is used to place the testis in the contralateral scrotum (Chacko et al., 2006; Thambidorai and Khaleed, 2008).

General Guidelines for Management

Surgical correction of cryptorchidism is indicated to optimize testicular function, reduce and/or facilitate diagnosis of testicular malignancy, provide cosmetic benefits, and prevent complications such as clinical hernia or torsion. Except in certain cases of associated complex medical illness or in the postnatal period, treatment should proceed after confirmation of the diagnosis. An algorithm has been established and published as part of the AUA Cryptorchidism guideline (Kolon et al., 2014) (see Fig. 46.6), which outlines the recommended approach to palpable and nonpalpable testes in patients confirmed to have an undescended testis by an experienced examiner. Similar guidelines have also been established by the Canadian Urologic Association and the European Association of Urology (Braga et al., 2017; Radmayr et al., 2016).

In infants, observation is indicated for the first 6 postnatal months to allow spontaneous testicular descent. If spontaneous testicular descent does not occur, surgical treatment after 6 months but preferably by 12 months of (corrected gestational) age is indicated. Support for this approach is based on the following rationale: (1) spontaneous descent is unlikely in full-term males after 2 to 6 months of age, (2) testicular growth is restored after early orchidopexy at 9 months as compared with 3 years of age, and (3) orchidopexy for abdominal testes may be easier in young infants, soon after mini-puberty. In boys with a history of prematurity, spontaneous descent may be delayed, and therefore observation should be continued for 6 months beyond the expected date of delivery or, especially if testicular position is marginal, until 1 year of age.

Despite these and prior guidelines which have progressively recommended younger ages at surgery, reports from diverse countries suggest that intervention is delayed in many children. For example, between 2001 and 2014, 20,275 boys were diagnosed with cryptorchidism in Sweden, but only 63% underwent surgery, and the median age decreased from 6.3 to 3.4 years during that interval (Bergbrant et al., 2018). The proportion having surgery in the first year of life remained low (~5%) although the total undergoing orchidopexy by 2 years of age increased from 10% to 30%. Similar reports from Australia (Schneuer et al., 2016b), the UK (Bradshaw et al., 2014), Germany (Hensel and Wirth, 2014), China (Wei et al., 2016), and multiple regions within the United States (Point et al., 2017; Savoie et al., 2017; Williams et al., 2017) found gradual reductions in the mean age at surgery yet delay beyond 2 years of age for the majority.

Although these studies could not differentiate between true delays in diagnosis (acquired cryptorchidism) and delayed treatment of congenital cases, intervention is often delayed in boys diagnosed at birth (Ellerkamp et al., 2018; Nah et al., 2014). Potential reasons for delay include lack of provider education, local resources, and/or socioeconomic factors, or likely, in some cases, recurrent cryptorchidism. Continued observation is needed after the occurrence of spontaneous testicular descent in infancy in light of the risk for testicular re-ascent.

Investigators in the Netherlands adopted an observational approach to boys with acquired cryptorchidism and reported spontaneous descent in 75 of 132 (57%) and 98 of 129 (75%) testes, respectively, most by mid-puberty (Eijsbouts et al., 2007; Sijstermans et al., 2006). The mean volume of descended testes in the study by Eijsbouts et al. was closer to those of normal contralateral testes as compared with boys who underwent orchidopexy. However, in both of these series, high scrotal testes comprised the majority of those that descended, and low scrotal "unstable" testes (likely retractile) were also included. On the other hand, Eijsbouts et al. reported that 19 of 82 unilateral cases had previous contralateral orchidopexy, and 10 boys required orchidopexy because of clinical hernia, pain, or torsion, suggesting a higher likelihood of true cryptorchidism in these cases. In follow-up studies of 391 boys with 464 acquired cryptorchid testes, 90% of high scrotal testes and 64.5% of inguinal/nonpalpable testes descended spontaneously at a mean age of 12.9 years (Hack et al., 2010). In contrast, a study from the same institution showed that testicular volumes were significantly smaller for age in 155 postpubertal patients who underwent orchidopexy at diagnosis (the majority before puberty) after a mean of 6.6 ± 3.8 years' follow-up (van der Plas et al., 2013c). Because these individuals were selected for orchidopexy and the majority (92%) had suprascrotal testes, they are likely not comparable to the group of boys treated after puberty at the same institution (Hack et al., 2010). These investigators obtained follow-up hormonal and semen analysis from 63 of 169 eligible men (49 unilateral, 14 bilateral) who underwent orchidopexy at diagnosis and 65 of 207 men who were observed for spontaneous descent (24 unilateral, 8 bilateral) or were observed initially but required surgery (51%; 26 unilateral and 7 bilateral) (van der Plas et al., 2015). Differences in the frequency of oligospermia, 27% and 38%, respectively, in operated versus observed unilateral cases, and 43% and 67%, respectively, in bilateral cases, were not statistically significant. These studies were not randomized, and many cases were lost to follow-up. Without adequate long-term paternity and malignancy outcome data, this approach cannot be recommended for cases of acquired, particularly bilateral cryptorchidism.

Medical Management

Hormonal therapy has been previously used for a variety of indications in patients with cryptorchidism, including differentiation of retractile from true undescended testes, stimulation of testicular descent, or germ cell maturation and as an adjunct to facilitate abdominal orchidopexy. In prospective series reporting the response of putative retractile testes to hCG, success rates vary from 58% to 100% and may be dependent not only on age, degree of retractility, and accuracy of diagnosis, but also on the dosage regimen used (Metin et al., 2005; Miller et al., 2003; Rajfer et al., 1986). These data suggest that hCG does not reliably distinguish retractile from cryptorchid testes, or eliminate the need for serial examinations in these patients.

Therapeutic LHRH and/or hCG

Luteinizing hormone–releasing hormone (LHRH) and/or hCG have been used as hormonal therapy to induce descent of testes for more than 70 years based on the premise that androgens promote testicular descent, but efficacy is questionable (Bu et al., 2016; Henna et al., 2004; Li et al., 2016; Pyorala et al., 1995; Thorsson et al., 2007). Although the efficacy of either hormonal treatment is about 20% and superior to placebo in randomized trials, this effect is not clearly clinically significant. Overall, the evidence from rigorous studies indicates that LHRH therapy is marginally more effective than placebo, and although not studied in randomized placebo-controlled trials because of its route of administration, hCG also shows limited efficacy. Other uses of hCG, including treatment of acquired cryptorchidism and to facilitate palpability and/or treatment of the abdominal testis (Baker et al., 2001; Bukowski et al., 2001; Polascik et al., 1996) also have limited efficacy. **Consequently, hormonal therapy to stimulate testicular descent is not currently recommended for treatment of boys with cryptorchidism** (Kolon et al., 2014; Thorsson et al., 2007).

The question of whether therapeutic hCG or LHRH protocols alter germ cell development has been addressed in several conflicting studies that are limited by small sample size, absent or suboptimal randomization, and variable availability of biopsy data (Ong et al., 2005). In small, retrospective studies, hCG treatment was associated with increased germ cell apoptosis at biopsy and lower adult testis volume (Dunkel et al., 1997), and previous hCG or LHRH therapy was associated with reduced germ cell counts in boys 1 to 3 years of age as compared with surgery alone (Cortes et al., 2000). In contrast, in a study of young boys (mean age 33 months, 21 per group) randomized to therapeutic doses of LHRH or no hormonal therapy before surgery, mean germ cell count was higher (1.05 ± 0.71) in LHRH-treated testes as compared with nontreated (0.52 ± 0.39) testes, with the effect enhanced in boys younger than 2 years of age (Schwentner et al., 2005). However, an additional recent report compared a more homogeneous group of boys who all underwent surgery before 2 years of age; 10 who had not responded to therapeutic LHRH (1.2 mg/day for 4 weeks) in a prior randomized study (De Muinck Keizer-Schrama et al., 1986) were compared with 14 who did not receive hormonal therapy (van Brakel et al., 2013). The authors found no differences in semen parameters or endocrine function between these two groups. In view of a lack of large prospective, randomized studies, it is unclear if specific types of hormone therapy for treatment of cryptorchidism are beneficial or harmful to germ cells in the short- or long-term. Future research in this area is unlikely, as this approach to treatment is no longer recommended.

Adjuvant Hormonal Therapy

Hadziselimovic et al. (1986, 1987a–c) were first to advocate the use of adjuvant or neoadjuvant LHRH agonist therapy to improve potential fertility in boys with cryptorchidism. The rationale for use of hormonal therapy to augment fertility potential is based on the premise that insufficient androgen stimulation, caused by “defective mini-puberty” or relative hypogonadotropic hypogonadism (Huff et al., 1989) is the cause of impaired transformation of gonocytes to Ad spermatogonia in neonatal cryptorchid boys and can be restored by gonadotropin stimulation later in childhood. No studies have directly tested this by hypothesis by directly correlating hormone levels in mini-puberty with spermatogonial development in control or cryptorchid individuals. However, existing data (see the Hormonal Defects section earlier in this chapter) do not confirm HPG axis defects in most cryptorchid infants. Moreover, age at scrotal placement of testes, but not LH, testosterone, FSH, or inhibin B levels, predicted higher germ and Sertoli cell counts at 9 months and 3 years of age (Kollin et al., 2012).

LHRH agonist (buserelin) therapy using a low-dose, long-term (10 or 20 mcg intranasally, every other day for 6 months) regimen to avoid HPG downregulation has been the primary approach used for stimulation of germ cell development, in conjunction with orchidopexy. In a retrospective study of nonrandomized, non–age-matched patients receiving buserelin versus surgery only, germ cell counts were significantly higher in the treated group (Hadziselimovic et al., 1987b). A subset of patients from this same cohort with the most severe testicular histology underwent re-biopsy after completion of therapy and were compared with a group of boys (8) of unknown age who required reoperative orchidopexy (Hadziselimovic et al., 1987a). A significant improvement in testicular histology was seen in the buserelin-treated group but not the surgical group. Similarly, in a smaller select group of boys treated with low doses of a related LHRH agonist, nafarelin, improved histology was observed in one or both testes at rebiopsy in 8 of 12 boys (Huff et al., 2001b). In a randomized study of clinically matched boys receiving buserelin + hCG, placebo + hCG, or surgery alone (19 to 25/group), germ cell counts were also significantly higher in those treated with buserelin (Bica and Hadziselimovic, 1992). In a nonrandomized retrospective study, buserelin-treated males, most of whom also received hCG, with a history of unilateral cryptorchidism and poor pretreatment germ cell counts had much higher sperm counts than patients who underwent surgery only (*n* = 15 per group) (Hadziselimovic, 2008). Unfortunately, these two groups were small and not clinically matched prospectively to limit other potential confounding factors, such as testicular position; and sperm counts in the surgery-only group were lower than typical for unilateral cryptorchidism.

Additional data from two randomized studies of boys with bilateral cryptorchidism were recently reported. In the first study, 10 boys (7 months to 3.5 years of age) with S/T counts 0.5 to 4.0 (normal considered 1.0, 0.65, and 0.38 at birth, 6 months, and 1 to 4 years, respectively) were included; testicular position was not stated (Thorup et al., 2018). Matched based on blinded germ cell counts, 5 received adjuvant LHRH, 200 mcg twice daily, every other day for 4 months beginning 9 months postoperatively, and 5 received no further therapy. At re-biopsy 12 months later, 2 LHRH-treated boys showed improvement in S/T counts to greater than 0.4 and 3 normalized Ad/T counts (>0.2). In the control group, 2 boys normalized both S/T and Ad/T, although mean S/T was higher in the LHRH-treated group. In the second study, 10 boys, 7 to 55 months of age at first surgery for bilateral cryptorchidism and nonblinded biopsy showing absent Ad spermatogonia, were computer-randomized to receive the adjuvant LHRH agonist (LHRHa) buserelin, 10 mcg intranasally, every other day for 6 months, followed by re-biopsy (Vincel et al., 2018). In the LHRHa group, all with inguinal testes, S/T rose after surgery and hormonal treatment to greater than or equal to 0.4 in 4 boys, and all developed measurable Ad/T values (0.005 to 0.02), although still below normal (≥0.1). In the surgery-only group, 3 with abdominal and 2 with inguinal testes, S/T rose to greater than 0.4 in 1 case, and none had visible Ad spermatogonia at the second biopsy. These pilot data suggest a potential role for adjuvant hormonal therapy in selected cases of bilateral cryptorchidism, but it is yet unclear which patients are most likely to benefit. Because Ad/T greater than 0.2 seems to be more predictive of future fertility than S/T (see later), it is also unclear whether the observed effects will translate to improved fertility in adulthood.

Recent reviews of the literature have addressed currently available data from these and other investigators, including the results of case-control (5), retrospective cohort (2), and randomized (3) studies (Biers and Malone, 2010; Chua et al., 2014). Using the Cochrane collaborative risk for bias assessment, the potential for bias was determined to be high or unclear in most domains analyzed for the randomized studies (Chua et al., 2014). The studies were highly variable with regard to patient age; sample size (range of 12 to 52 per treated group); type, dose, timing, and duration of therapy used; outcome criteria, and blinding. In some series, both hCG and either adjuvant or therapeutic doses of LHRH were used, and some patients in control groups also received hormones. Although these data suggest potential efficacy of adjuvant therapy in improving fertility potential, the methodologic limitations make interpretation difficult, and therefore adjuvant therapy is not widely in use. **Large, well-designed studies of bilateral cryptorchidism, for which this approach may be most useful, that use standardized treatment regimens, and report fertility and paternity outcome measurements, are needed.**

Surgical Management

The recommendation that surgical intervention proceed once failure of spontaneous descent is confirmed is now standard (Chan et al., 2014; Kolon et al., 2014) but is not new. Retrospective studies that address the question of whether early surgery is preferable have shown mixed results, and, particularly in view of the heterogeneity of the disease, are difficult to interpret. However, the prospective, randomized study by Kollin et al. (2007, 2012) suggests that surgery in the first year of life in cases of congenital cryptorchidism is likely to be beneficial with regard to testicular growth and histology, although long-term outcome data are not available. Despite long-standing recommendations for surgery in infancy in cases of congenital cryptorchidism, the median or average age at which orchidopexy is performed remains 1.5 to 4 years in many series (Barthold and González, 2003; Barthold et al., 2012; Bayne et al., 2011; Bradshaw et al., 2014; Kokorowski et al., 2010; Nah et al., 2014; Snodgrass et al., 2011). A review of the Pediatric Health Information System (PHIS) database by Kokorowski et al. demonstrated that only 18% of 28,204 boys who underwent surgery did so by 1 year of age. The reason for later surgery likely reflects a combination of factors, primarily delayed referral of congenital cases and new diagnoses of acquired cryptorchidism. Cases of congenital cryptorchidism may go undetected or untreated in infancy because of prematurity or other morbidity, undergo longer than necessary observation for spontaneous descent, or represent cases of undetected re-ascent after spontaneous descent in infancy. Delay may also be exacerbated by difficulty in distinguishing undescended from retractile testes.

A treatment option for **pubertal and postpubertal boys** is orchiectomy, especially if the testis is abdominal or difficult to mobilize because poor spermatogenesis and hypotrophy are usually present and the risk for carcinoma in situ and torsion exist (Chung and Lee, 2015; Rogers et al., 1998). A testicular prosthesis may be placed at the same setting if desired.

Palpable Testes

Inguinal Orchidopexy

The traditional approach to surgical treatment of palpable testes is inguinal orchidopexy (Video 46.1) with repair of an associated hernia if present (Hutcheson et al., 2000a), although a primary scrotal approach as originally described and advocated by Bianchi et al. is an increasingly popular approach (Bianchi and Squire, 1989; Iyer et al., 1995).

After induction of anesthesia, the patient is re-examined to confirm that the testis is palpable and to identify the lowest testicular position. In the standard inguinal approach, a low transverse incision in Langer's lines at or below the inguinal crease is made superolateral to the pubic tubercle. Dissection of the subcutaneous tissue should include a search for a testis within the superficial inguinal pouch. After identifying the external ring, the external oblique fascia is incised to expose the canal with care to avoid injury to the ilioinguinal nerve. Testis position is recorded relative to the inguinal canal. The spermatic cord is isolated, and the testis is dissected distally to its attachment to the gubernacular remnant. Transection of the gubernaculum distal to the sac will avoid potential injury to a long-looping vas. Longitudinal incision of the internal spermatic fascia allows free mobilization of an intact hernia sac, if present, and minimizes skeletonization of the vas and spermatic vessels. Alternatively, the sac may be opened overlying the testis and the incision extended proximally along the length of the cord. Once isolated, the sac is mobilized to the level of the internal inguinal ring and suture-ligated. Incision of the internal spermatic and transversalis fascia at the level of the ring facilitates additional retroperitoneal mobilization of the vas and vessels, if needed. Further maneuvers to provide spermatic cord length include transection of lateral fascial bands along the cord, cranial retroperitoneal dissection, medial transposition of the testis beneath the epigastric vessels (Prentiss maneuver), and, if required, cranial extension of the incision. Very rarely, the testis cannot be brought to dependent scrotal position after these maneuvers, and a two-stage procedure may be considered as an alternative to orchiectomy, which is preferentially reserved for visibly abnormal or atrophic testes, postpubertal patients, or cases associated with insufficient vasal length.

After mobilization of the spermatic cord, a transverse scrotal incision is made and a subdartos pouch created. A large clamp or a finger can be used to create a tunnel just anterior to the pubis. The testis is passed through an opening in the dartos without twisting of the spermatic cord. Existing appendages should be excised and the epididymis inspected and any anomalies recorded. Recording of testicular volume by measurement in three dimensions and similar (estimated) measurements of contralateral testicular volume can establish a baseline for postoperative assessment. Secure fixation of the testis within the pouch can be achieved by tension-free closure of the opening in the dartos around the cord, incorporating the cut edge of the tunica vaginalis. If needed, additional fixation sutures can be placed between the visceral tunica vaginalis and the dartos. Alternatively, suture fixation through the tunica albuginea to the scrotal wall may be performed. There is a theoretical risk for injury to the testis, however, via inflammatory or vascular insult with suture placement through the tunica albuginea. Closure is completed with absorbable sutures. Supplemental local or regional techniques for perioperative pain control are advisable and may include local anesthetic infiltration, ilioinguinal nerve block, or caudal anesthesia; the latter is particularly useful in younger patients undergoing bilateral inguinal or concomitant penile surgery.

Testicular biopsy has been performed routinely is some centers and has been advocated by Hadziselimovic et al. (2007) as a method to determine prognosis for fertility. This approach is controversial and has not been recommended for routine use outside of research protocols because it does not change the current approach to treatment (Beckers et al., 2008; Ritzen et al., 2007). Increasingly, however, other investigators suggest that biopsy be considered in cases of bilateral cryptorchidism as a method to identify individuals who lack Ad spermatogonia and are potential candidates for gonadotropin therapy, and to identify CIS in males older than 13 years of age, using available protein markers (Biers and Malone, 2010; Cortes et al., 2016a; Faure et al., 2016; Mechlin and Kogan, 2014; Thorup and Cortes, 2016; Thorup et al., 2018; Verkauskas and Hadziselimovic, 2016; Verkauskas et al., 2016) (see the Prognosis section later in this chapter). The risk to the cryptorchid testis from biopsy is theoretical; although long-term effects do not appear to include increased risk for microlithiasis or antisperm antibody formation (Patel et al., 2005), other more subtle effects cannot be excluded from the available data. Biopsy is indicated in cases of sexual ambiguity or if clinical evidence of testicular dysgenesis is present.

Complications of inguinal orchidopexy are uncommon; those of greatest significance include testicular retraction and atrophy. Docimo (1995) reported a comprehensive review of the orchidopexy literature in 1995, before the routine use of laparoscopic orchidopexy, and including both palpable and nonpalpable testes. He concluded that the overall risk for atrophy or nonscrotal position was approximately 15% overall in published reports, significantly higher in abdominal or peeping testes (24%) compared with those distal to the internal ring (10%) and higher in boys operated after 6 years of age. More recently, analysis of boys presenting with postoperative testis retraction over an 18-year period at a single institution composed less than 2% of 1886 primary open orchidopexies performed during that period, with a slightly higher risk for failure in older boys (McIntosh et al., 2013). However, these boys were not actively followed by the authors, so detailed clinical data were not available, and the frequency of testicular atrophy could not be defined. In another series of 418 orchidopexies in 356 boys from a single institution with a median of 1 year follow-up, the risk for atrophy was 1.9% and of nonscrotal position was 10.3% (Thorup et al., 2011a). However, in this series the risk for complications was higher when surgery was performed at a younger age, and all boys with acquired cryptorchidism had a successful result. The authors conclude that earlier orchidopexy may be more technically demanding, and support the concept that expertise of the surgeon is relevant for more challenging cases.

A minimum of 6 months' follow-up is recommended to determine postoperative testis position and size. Long-term follow-up should be considered for counseling of the patient regarding fertility issues, risk for testicular malignancy, and self-examination. Torsion of a scrotal testis after orchidopexy has been reported but is very rare, and the risk may be minimized by routine extravaginal testicular fixation in a subdartos pouch. If complete intrascrotal testicular atrophy occurs postoperatively, further intervention is not needed, but the option of testicular prosthesis placement should be offered to the patient and family (Bodiwala et al., 2007). Implantation of a testicular prosthesis should occur at least 6 months after any scrotal procedure or after puberty, and is best performed through an inguinal approach. Fixation of the prosthesis to the dartos and closure of the scrotal fascia above the implant using purse-string nonabsorbable suture is required. Risks including displacement, pain, or infection occur in less than 5% of cases. Clinical experience suggests that cryptorchid boys request prosthesis implantation less frequently than males with acute testicular loss after puberty (Bodiwala et al., 2007).

Reoperation is indicated if a testis is nonscrotal after orchidopexy. If the testis is prescrotal, a primary scrotal approach can be considered and may allow adequate mobilization of the testis. If inguinal exploration is needed to provide sufficient cord length, several approaches are available. Redman (2000) described an approach for primary or secondary orchidopexy that involves a lateral approach to the cord after mobilization of the external oblique and cremaster fasciae. This approach avoids traversal of the previously scarred layers anterior to the cord and a clearer view of the anatomy. Cartwright et al. (1993) described mobilization of the intracanicular cord with an overlying patch of external spermatic fascia. The importance of correcting a persistently patent processus vaginalis and/or of adequate retroperitoneal mobilization of the cord in cases of high recurrent cryptorchidism has been stressed (Pesce et al., 2001; Redman 2000; Ziylan et al., 2004). The results of secondary orchidopexy appear to be similar to the primary procedure, although the risk for vascular and vasal injury is theoretically higher (Pesce et al., 2001).

Transscrotal Orchidopexy (▶*Video 46.2)*

A primary scrotal approach can be considered when the testis is palpable (Bianchi and Squire, 1989; Cloutier et al., 2011; Iyer et al., 1995), although some surgeons reserve this approach for testes that are close to or can be drawn into the scrotum (Bassel et al., 2007; Rajimwale et al., 2004; Russinko et al., 2003; Takahashi et al., 2009). After induction of anesthesia, the patient is re-examined to confirm the position of the testis. An incision along the superior scrotal border is made as described by Bianchi et al. for any palpable testicles. Alternatively, a transverse low scrotal approach (Misra et al., 1997) and midline scrotal approach (Cloutier et al., 2011) have been described for those testes that can be drawn into the scrotum (Fig. 46.11). After the testis is delivered, the distal sac and overlying cremaster are mobilized proximally as far cranially as possible, “high above the inguinal canal” (Iyer et al., 1995). Some cases require conversion to an inguinal approach for ligation of the sac or to gain further length on the spermatic cord (Dayanc et al., 2007; Parsons et al., 2003). Rajimwale et al. (2004) confirmed in several cases that the hernia sac had been effectively ligated above the internal ring via the scrotal incision when a secondary inguinal incision was required for further mobilization of the testis. Fixation sutures through the tunica albuginea were used in many series of scrotal orchidopexy (Bassel et al., 2007; Dayanc et al., 2007; Jawad 1997; Russinko et al., 2003; Takahashi et al., 2009) followed by placement of the testis in a subdartos pouch. In an extensive review of the literature by Gordon et al. (2010), additional inguinal incisions were needed in 4.4% of cases, and there were early postoperative complications in 1.6% of cases. The single-institution long-term results reported by these authors included a reoperative rate of 4.9% and 0.6% incidence of testicular atrophy. In a literature review of 1558 cases in 20 series reporting 3 months to 5 years of follow-up, a hernia was present in 30% of cases, and 3.5% of cases required an inguinal incision (Novaes et al., 2013). Complications included recurrence

(0.6%), testicular atrophy or hypotrophy (0.3%), hematoma (1.4%), wound infection (0.8%), and vasal injury (1 case) with a low overall complication rate of 3%. **Scrotal incision orchidopexy is used selectively in many series, but the available evidence suggests that efficacy and complication rates are similar to standard inguinal orchidopexy.** Increasingly, the scrotal approach is advocated as a first choice for all palpable testes (Arena et al., 2016; Feng et al., 2016; Gordon et al., 2010).

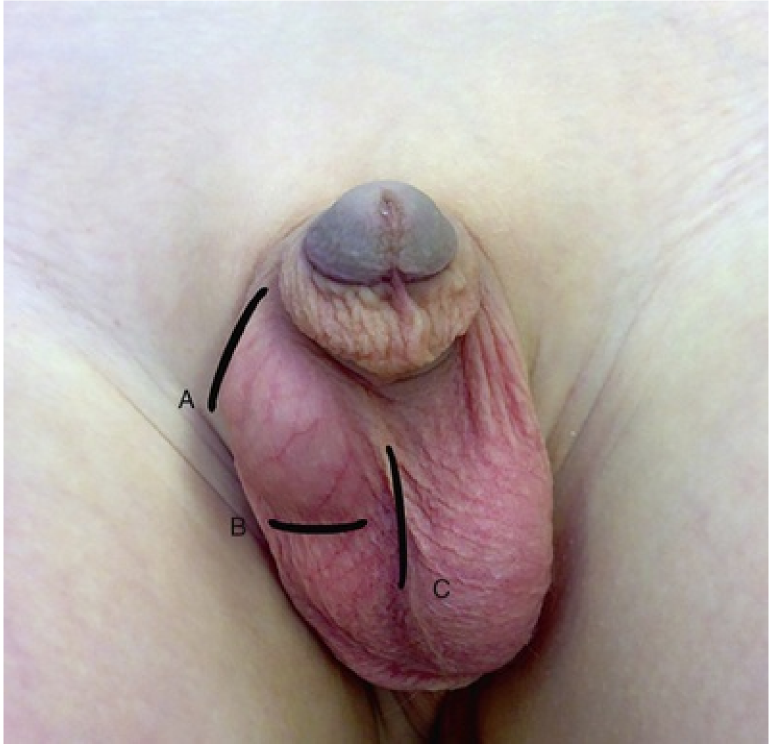

FIG. 46.11 Transscrotal orchidopexy. Various scrotal incisions that have been reported; (A) Bianchi incision (Bianchi). (B) Transverse low scrotal approach (Misra). (C) Midline scrotal approach (Cloutier).

Abdominal Testes

Once an abdominal testis has been identified, the surgeon must decide whether to proceed with an open or laparoscopic, one- or two-stage orchidopexy with possible spermatic vessel transection. Orchiectomy is appropriate for patients with testes that are poorly viable and/or at higher risk for tumor, which may include testes in postpubertal patients or very small or dysgenetic testes in postpubertal patients, and is in the opinion of these authors best performed laparoscopically.

Open Transabdominal Orchidopexy

Extensive dissection of the vas and vessels is facilitated by a longitudinal opening of the internal oblique and peritoneum through an extended inguinal incision (Kirsch et al., 1998) or via a higher incision medial to the pubic tubercle and a preperitoneal approach (Gheiler et al., 1997; Jones and Bagley, 1979). In the procedure described by Jones and Bagley, the internal ring is approached via a muscle-splitting incision, the peritoneum is opened, the testis is delivered, and the vas and vessels are freed from their peritoneal attachments. A tunnel is created to the scrotum, and the testis is secured in place as for an inguinal orchidopexy. The reported success rate for this procedure for abdominal testes was 95% (Gheiler et al., 1997).

Laparoscopic Orchidopexy and Fowler-Stephens Orchidopexy *(▶Video 46.3)*

Operative laparoscopy emerged over 25 years ago as the procedure of choice for abdominal orchidopexy (Caldamone and Amaral, 1994; Jordan et al., 1994), and the basic surgical approach and high success rates have stood the test of time. The feasibility of primary versus Fowler-Stephens orchidopexy depends on the length of vas and vessels, presence/absence of looping ductal structures, and patient age. Laparoscopy allows the surgeon to assess some of these features before choosing a specific surgical procedure, but the choice may be difficult (Shepard and Kraft, 2017; Yucel et al., 2007). Observed testicular position alone may correlate poorly with the ultimate length of the cord after mobilization.

After induction of anesthesia, a further attempt to palpate the testis is made, although a laparoscopic approach may be considered for mobilization of high canalicular testes as well. After decompression of the bladder and stomach, an infraumbilical 5-mm trocar is placed for passage of a 30-degree lens, and both internal rings are visualized. An open Hasson or Bailez technique is preferable for umbilical trocar placement in the pediatric age group to minimize the risk for injury (Franc-Guimond et al., 2003). CO_2 pneumoperitoneum to a maximum pressure of 8 to 12 mm Hg is used. The size and position of the testis within the abdomen is determined before further decision making. For single-stage laparoscopic orchidopexy, additional 2- or 3-mm trocars are placed in the right and left lower quadrants to triangulate with the umbilicus and ipsilateral internal ring, or in the midclavicular line at the level of the umbilicus bilaterally for bilateral abdominal testes. The major steps are mobilization of any structures extending distal to the internal ring, including epididymis/vas and gubernacular remnant; transection of the peritoneum lateral to the vessels and distal to the vas; and proximal mobilization of the vessels while maintaining collateral blood supply between the vas and spermatic vessels. Samadi et al. (2003) advocate initial mobilization of the gubernaculum to be used as a handle for further mobilization of the testis, and minimal use of cautery during this maneuver. Ability to mobilize the testis to the opposite internal ring has been used as a measure of adequate length for placement in the scrotum, but is not predictable in some series. Once mobilized, the testis is brought through a new hiatus medial to the epigastrics and lateral to the medial umbilical ligament or through the existing internal inguinal ring. This maneuver can be completed using a trans-scrotal clamp or an additional port passed up from the scrotum. With tension on the extra-abdominal testis, peritoneal attachments overlying the cord can be more easily transected, thus providing additional length. In some cases, the testis can only be brought into the upper scrotum; the long-term adequacy of this approach is not clear. Excessive tension on the vessels during placement of the testis should be avoided, as injury or avulsion of the spermatic vessels may occur (Esposito et al., 2002). A key strategy should be preservation of the blood supply between the vas and spermatic artery during dissection so that the Fowler-Stephens procedure can be performed if necessary.

Formal closure of the dissected internal ring is not necessary (Handa et al., 2005; Riquelme et al., 2007); indeed, previous experience with open hernia repair suggests that ligation is not needed if the internal ring is dissected (Mohta et al., 2003). No inguinal hernias were identified a mean of 41 to 50 months after laparoscopic orchidopexy in a retrospective series in which formal closure of the internal ring was performed in 54% of cases (Khairi et al., 2013). A contralateral patent processus vaginalis was identified in 9% of boys undergoing laparoscopic orchidopexy in one series, and laparoscopic repair was performed and recommended (Palmer and Rastinehad, 2008). However, the necessity for this approach in preventing clinical hernia formation is questionable based on studies of boys undergoing laparoscopic or open hernia repair (Schier, 2007).

For testes that are not near (variably defined as 2 to 4 cm above) the internal inguinal ring, transection of the spermatic vessels as originally described by Fowler and Stephens may be necessary (Fowler and Stephens, 1959); a long-looping vas facilitates but is not required for testicular mobilization to the scrotum. The Fowler-Stephens procedure is now typically performed laparoscopically with spermatic vessel clipping (Bloom 1991) followed by laparoscopic or open testicular mobilization in the same setting, or in a staged approach 6 months later. The peritoneum should be left intact over the vasal vessels, and the gubernacular vessels should be left intact if possible. Although most surgeons transect the spermatic vessels at least 1.5 to 3 cm above the testis, Koff and Sethi (1996) proposed that ligation close to the testis is preferable. This group subsequently studied the effect of low- versus high-transection of the vessels in prepubertal rats and showed a reduction in adult testicular sperm numbers that was similar in both groups (Srinivas et al., 2005). In human studies, testicular biopsies before and after spermatic vessel transection also showed a reduction in germ cell count, a finding that was significant in younger boys (Rosito et al., 2004; Thorup et al., 1999). In general, the preferred approach is avoidance of spermatic vessel transection whenever possible; the available data suggest this is possible in the majority of cases of abdominal orchidopexy. In rare cases, particularly if the testis is retrovesical, the vas is too short to allow scrotal placement of the testis, and orchiectomy is ultimately required (Perovic and Janic, 1997).

The success rates for laparoscopic procedures has been extensively reported over the past 20 years (Alagaratnam et al., 2014; Alam et al., 2017; Bagga et al., 2018; Baker et al., 2001; Bracho-Blanchet et al., 2016; Casanova et al., 2013; Chang and Franco, 2008; Denes et al., 2008; Erdoğan et al., 2017; Esposito and Garipoli, 1997; Esposito et al., 2002; Handa et al., 2005; Hay et al., 1999; Jordan et al., 1994; Kaye and Palmer, 2008; Lotan et al., 2001; Radmayr et al., 2003; Robertson et al., 2007; Samadi et al., 2003; Stedman et al., 2015; Wayne et al., 2015; Yucel et al., 2007) and still appear to compare favorably with the corresponding 74%, 63%, and 77% overall success rates for open surgical one- and two-stage Fowler-Stephens procedures, respectively, that were reported early on after the inception of laparoscopy (Docimo, 1995). The available data suggest that a primary procedure is more consistently successful (>90% in most series) as compared with a Fowler-Stephens approach (variable success of 60% to 97%). In directly comparing the results of 156 abdominal orchidopexies at a single institution, Stec et al. observed significantly more favorable results for a primary open (89% success) or laparoscopic (97%) approach as compared with one-stage (63%) or two-stage (68%) Fowler-Stephens procedure (Stec et al., 2009). Variation in reported results among series may reflect inherent selection bias resulting from differences in patient age, testicular position or quality, length of follow-up, and/or criteria used to define success, such as “intrascrotal” versus “dependent scrotal” position. In a meta-analysis, Elyas et al. (2010) calculated a slightly better pooled estimate for success of two-stage as compared with one-stage Fowler-Stephens orchidopexy, irrespective of primary (open or laparoscopic) approach, but again note that the quality of the included studies was low. More recent studies have shown no difference in atrophy rates between one- and two-stage Fowler-Stephens orchidopexy, but there may be better positioning after a two-stage approach (Alam et al., 2017; Bagga et al., 2018; Ostlie et al., 2015). **Despite their limitations, the available data seem to suggest that primary orchidopexy without transection of the spermatic vessels is preferable whenever possible.** Some authors recommend that ultrasonography be used to confirm testicular viability postoperatively (Esposito et al., 2002). Other complications of laparoscopic orchidopexy are rare and potentially include bladder or vascular injury, hypercapnia, and delayed small bowel obstruction (Esposito et al., 2003; Hsieh et al., 2009; Riquelme et al., 2015).

Laparoscopic techniques may be applicable in unusual cases, including bilateral orchidopexy, abdominal wall defects, polyorchidism, splenogonadal fusion, and transverse testicular ectopia with or without persistent müllerian ducts. Many authors recommend simultaneous bilateral abdominal orchidopexy (Kaye and Palmer, 2008), but the surgeon should consider a staged approach if both testes are very high or the viability of a testis is questioned during the course of orchidopexy as noted in their algorithm. Depending on the outcome of the first procedure at 6-month follow-up, the surgeon can choose an operative approach to the contralateral side that would appear to minimize the risk for bilateral testicular atrophy (Thorup et al., 2007). Some surgeons have considered microvascular orchidopexy to be a preferred approach to the solitary abdominal testis, particularly with historical success rates of 88% as compared with lower rates for open procedures (Docimo, 1995). At a center with substantial experience using the microvascular approach, long-term success rates of 96% for standard and 88% for laparoscopically-assisted autotransplantation were reported (Bukowski et al., 1995; Tackett et al., 2002). The advantage of this approach is preservation of the spermatic vessels, at the cost of longer operative time and requirements for an experienced microvascular surgeon and hospital stay.

Prognosis

Despite its common occurrence and voluminous literature on the subject of cryptorchidism, many gaps exist in our present understanding of the factors contributing to long-term outcome. This is likely a result of the expectation that surgical correction will be successful in most cases, and prospective studies into adulthood are difficult and not routine in otherwise healthy males. These studies would need to (1) account for multiple confounding variables, many that are incompletely defined, including severity of the disease (based on testicular position, laterality, epididymal anomalies, hormone profiles), multifactorial etiology, age at surgery, exposure to hormone therapy, and type of procedure performed, and (2) use standardized methodology based on adequate follow-up and complete documentation of complications to report results. Well-designed studies providing high-quality evidence are clearly needed.

Fertility

There is strong evidence that a history of cryptorchidism is associated with the risk for subfertility or infertility, particularly in bilateral but also in unilateral cases (Schneuer et al., 2018; Thorup and Cortes, 2016). Conversely, cryptorchidism is one of the most common antecedent factors in men evaluated for infertility, composing up to 10% to 17% of that population (Olesen et al., 2017; Paasch et al., 2004; Schneuer et al., 2018). Subfertility risk is difficult to predict in individual patients, because multiple factors likely contribute including presumably diverse etiologies, age at diagnosis and treatment, approach to treatment, and/or severity of disease. Major limitations in the interpretation of cryptorchidism outcome studies include the selection bias that occurs when follow-up includes less than one-third of eligible cases, who may self-select, and the results of a single semen analyses that may not accurately predict paternity. In a large review of retrospective studies published in the 50 previous years that did not take these limitations into consideration and did not include a statistical meta-analysis, Chilvers et al. (1986) reported that 42% and 31% of men with former bilateral, and 31% and 14% with unilateral cryptorchidism developed oligospermia and azoospermia, respectively. The limited available data comparing earlier treatment (age <9, 45% of cases) and later treatment did not show differences in the frequency of subfertility after unilateral (281 cases) or bilateral (123 cases) orchidopexy. Similarly, subset analysis failed to identify any effect of hCG treatment, which was used in 42% of patients. The observation that azoospermia occurs in unilateral cryptorchidism is consistent with data showing that germ cell development is abnormal in some contralateral descended testes. However, the frequency appears lower in studies of previously cryptorchid men (0% to 10%), as compared with subjects accrued from infertility clinic populations (11% to 28%) (Hadziselimovic et al., 2011; Rohayem et al., 2017). In contrast, Schneuer et al. (2018) demonstrated in a population-based cohort study of 7499 boys with cryptorchidism that surgery before 18 months reduced the need for assisted reproductive technologies (ARTs), but for every 6-month delay in treatment there was a 5% increase in the future need for ART.

Subsequent reports of semen parameters in large series of men who underwent orchidopexy in childhood also found differences between bilateral and unilateral cryptorchidism but less consistent overall results. In general, outcomes were not consistently related to childhood hormone therapy, adult hormone levels, prior testicular position, or age at surgery, although the mean or median age of surgery in many reported series was high, typically 6 years or older. Gracia et al. (2000) reported normal semen samples in only 57 of 171 (33%) men with previous unilateral and 10 of 55 (18%) men with a history of bilateral cryptorchidism who underwent surgery at a mean age of 6.4 years. Kraft et al. (2012) reported normal sperm counts after unilateral orchidopexy in 60% of 85 men, and after bilateral orchidopexy in 18% of 17 men with surgery performed at a mean age of 7.0 years. Cortes et al. (2003a) found very low sperm counts (<5 million/mL) in 9% of 65 unilateral and 54% of 70 bilateral cases who underwent surgery at a median age of 10.8 and 12.7 years, respectively. Of 108 patients who underwent unilateral orchidopexy between 6 and 12 years of age, 31% had a normal sperm concentration (Ponchietti and Grechi, 1986). In 91 patients with unilateral cryptorchidism who underwent orchidopexy after the onset of puberty (14 to 29 years of age), normospermia was present in only 16% (Grasso et al., 1991).

Other studies suggest more encouraging long-term results. Okuyama et al. (1989) reported normal sperm density based on 3 semen analyses in 0%, 72%, 77%, and 42% of men after bilateral orchidopexy (61), unilateral orchidopexy (149), unilateral orchiectomy (26), and no treatment (38). Puri and O'Donnell (1988) studied 142 men who underwent unilateral (119) or bilateral (23) orchidopexy at 7 years of age or older and reported normal sperm density in 84% and 50% of cases, respectively. Similarly, testicular atrophy or Sertoli cell–only histology was present in 179 of 222 (81%) adults who underwent orchiectomy for unilateral cryptorchidism, but of 97 in this series who had semen analysis, 61% and 5% had normospermia and azoospermia, respectively (Ates et al., 2016). In a small series of 51 men who had orchidopexy before 2 years of age, a normal sperm count was reported in 96% of unilateral (27) and 75% of bilateral (24) cases (Feyles et al., 2014). Hence, it appears that the quality of germ cell development in the descended testis of cases of unilateral cryptorchidism, and other unmeasured factors in cases of bilateral cryptorchidism, are major determinants of fertility potential.

Mean germ cell counts obtained at biopsy correlate with long-term fertility potential as measured by mean semen analysis parameters in some series (Cortes et al., 2003a; Engeler et al., 2000; Rusnack et al., 2003) but not in others (Hadziselimovic and Herzog, 2001; Hadziselimovic et al., 2008; Kraft et al., 2011, 2012). The wide variation in sperm concentrations reported, particularly in association with abnormal histology (Kraft et al., 2012), suggests that the utility of total germ cell counts as a predictor of fertility at the individual level is limited. More recent reports investigated the use of Ad spermatogonia number as a better predictor of semen quality in adulthood. Hadziselimovic et al. reported a strong correlation between the number of Ad spermatogonia in cryptorchid testes and sperm count in adulthood after previous unilateral or bilateral orchidopexy with or without prior hormonal therapy (Hadziselimovic and Herzog, 2001; Hadziselimovic et al., 2007, 2008). In nonhormonally treated cases, total sperm count was normal (>40 million/ejaculate) in 84% of 25 men who had Ad spermatogonia present in biopsies from both testis, and it was subnormal in all 18 men (10 of the 19 men in this series with a history of bilateral cryptorchidism) in whom biopsies were negative for Ad spermatogonia (Hadziselimovic and Hoecht, 2008). Of subjects with bilateral cryptorchidism and Ad spermatogonia in one or both testes, 55% had a normal sperm count. In a larger series of men with prior unilateral (91) or bilateral (19) cryptorchidism, Kraft et al. (2012) observed lower mean sperm counts and higher FSH levels in adulthood when bilateral biopsy at surgery showed severe loss of germ cells or abnormal Ad spermatogonia counts, but likely because of the variability of the data, group means remained within normal range and/or were not statistically significant, confirming that even analysis of Ad spermatogonia does not always predict individual fertility potential. In view of the heterogeneity of the disease and its treatment, most studies are likely underpowered to detect clear associations between histologic and phenotypic variables and fertility potential as estimated by semen analysis. **Nevertheless, both Ad spermatogonia count and germ cell absence are potentially useful measures of fertility prognosis, but may be more useful in cases of bilateral cryptorchidism.** Additional, larger prospective studies of these parameters in boys undergoing surgery in infancy are needed.

The use of semen analysis alone to define outcome and predict fertility potential has limitations. For example, a large population study of fertile and infertile men with fertile partners suggests that there is large overlap between semen parameters in men with and without proven paternity (Guzick et al., 2001). In this study, the authors established lower infertile threshold levels for density (13.5×10^6/mL), motility (>35%), and normal morphology (>9%) than had been established by World Health Organization criteria. About 3% of fertile men in this series had a sperm density less than 10×10^6/mL, and measurements between 13.4 and 48×10^6/mL were considered indeterminate. Repeated semen analyses, rarely obtained in studies of formerly cryptorchid men, were reportedly necessary to provide reliable data in normal men (Oshio et al., 2004). However, the reliability of semen analysis in adolescents is not fully known. Christman et al. (2013) recently addressed this question in Tanner stage V youths (<25 years of age) being evaluated for cryptorchidism (48) or varicocele (31). In this study, semen parameters were not highly reproducible between samples in the same individual, yet the computed intraclass correlation coefficient was considered substantially reliable, particularly for total sperm counts, suggesting that a single sample, especially when normal, may suffice in estimating fertility potential. When semen analysis results are abnormal, repeat samples should be obtained whenever possible.

Paternity status may be a more helpful measure of fertility that should be considered when determining prognosis. Limitations of this approach include paternal discrepancy, female factors, and variability in the timing and degree of interest in attempts at paternity, which may be based on age, marital status, and so on. Although of concern and not ethically retrievable, a recent review (Bellis et al., 2005) found that the median level of paternal discrepancy in 17 studies of unselected populations in Europe and the Americas is only 3.7% (interquartile range, 2% to 9.6%). Two retrospective cohort studies of men with previous cryptorchidism assessed paternity in 145 (Gilhooly et al., 1984) and 40 (Cendron et al., 1989) cases. Together, these studies identified successful paternity in 100 of 123 (81%) men with a history of unilateral and 19 of 54 (35%) men with a history of bilateral cryptorchidism. Lee et al. published a series of well-designed case-control studies of fertility in cryptorchidism (Coughlin et al., 1999; Lee and Coughlin, 2001, 2002; Lee et al., 1996, 1997, 2000, 2005). Questionnaire, hormone, semen analysis, and paternity data were analyzed for a large cohort of men who underwent orchidopexy between 1955 and 1975 and a control group of similar age who were matched for timing of unrelated surgery. For all married or cohabitating men, 32 of 88 (36%) former bilateral, 322 of 609 (53%) former unilateral, and 413 of 708 (58%) controls had fathered children. **Of those attempting paternity, 32 of 49 (65%) former bilateral, 322 of 359 (90%) former unilateral, and 413 of 443 (93%) controls were successful.** There were no significant differences between the unilateral and control groups and no differences between groups in the frequency of attempted paternity or in other lifestyle factors that may adversely affect fertility. The frequency of successful paternity did not differ between men with previous unilateral cryptorchidism who had undergone orchiectomy and the control group. The RR for infertility was increased after hCG treatment (RR 4.7, $P = 0.002$), but not with higher testicular position or age at orchidopexy. Sperm density was less than or equal to 13×10^6/mL in all 8 patients with bilateral cryptorchidism who were studied; however, 3 of these men had fathered children (Lee and Coughlin, 2001). Sperm density and motility were normal in 83% of men in the unilateral group, and morphology did not differ from control values. The authors concluded that prediction of infertility is difficult in the absence of azoospermia or severe oligospermia.

In limited series, investigators have addressed the possibility of defective spermatogenesis in adult patients with persistently retractile testes or with milder forms of acquired cryptorchidism, with or without apparent spontaneous descent of the testis at puberty. In small, retrospective outcome studies, Puri and Nixon (1977) reported 74% paternity and normal testicular volume in a series of 43 adults with untreated retractile testes in childhood. Conversely, Nistal and Paniagua (1984) and Caroppo et al. (2005) identified 23 and 34 males, respectively, from infertility clinic data and identified poor semen parameters in the majority of cases, but the duration and severity of retractility were poorly documented. Two series reported varying degrees of abnormal germ cell or Sertoli cell development in retractile testes of boys who underwent elective orchidopexy as compared with boys with descended testes; differences were qualitatively similar to findings in cryptorchid testes (Caucci et al., 1997; Hadziselimovic et al., 1987a). Han et al. (1999) compared 61 retractile with 83 cryptorchid testis biopsies and noted similar trends but did not include a control group. Methodologic limitations prevent clear differentiation of retractile from acquired undescended testes in these studies. Prospective studies of well-characterized patients are needed, but there is insufficient evidence to support an increased risk for infertility in uncomplicated cases of retractile testis.

Similarly, the outcome data for acquired cryptorchidism are difficult to interpret, because to date they are based on retrospective, nonrandomized studies that analyzed cases of both spontaneous descent at puberty and prior orchidopexy. In a retrospective series of 45 adults with spontaneous descent of bilaterally undescended testes after 10 years of age by history (without clear documentation of congenital vs. acquired classification), testicular volumes were less than 15 mL in 62%, and sperm counts were below 20 million/mL in 44% of patients (Bremholm Rasmussen et al., 1988). Investigators from the Netherlands who have followed boys with either congenital or acquired cryptorchidism reported follow-up fertility data (van Brakel et al., 2013, 2014). In prior publications from these institutions, the majority of the acquired group, particularly those with spontaneous descent at puberty, included high scrotal and low scrotal "unstable" testes (likely retractile) (Eijsbouts et al., 2007; Hack et al., 2010; Sijstermans et al., 2006). Van Brakel et al. (2013, 2014) observed no differences in semen parameters or hormone levels in small subgroups of men with a history of acquired cryptorchidism after spontaneous testicular descent (24) or orchidopexy (26) at puberty. Of 62 men with prior congenital cryptorchidism, the majority (89%) unilateral, 33% and 57% of unilateral and bilateral cases, respectively, had oligospermia, and none had azoospermia. Of 65 men with a history of acquired cryptorchidism, 39% and 8% of prior unilateral, and 71% and 7% of prior bilateral cryptorchid men had oligospermia and azoospermia, respectively. There were no significant differences in semen parameters between acquired and congenital cryptorchidism, or between observed and surgically treated subsets of the acquired group. These data provide further support for a shared etiology for congenital and acquired cryptorchidism.

The available data indicate that fertility potential is compromised in many men with a history of bilateral cryptorchidism, but abnormal semen parameters and/or abnormal spermatogonial differentiation in unilateral cases suggest an increased risk for infertility that is not supported by available paternity data. However, much of the available evidence suggests a congenital cause for subfertility that affects both testes in males with cryptorchidism that may not be abrogated by surgery alone, although early surgery is preferred and may be beneficial (Thorup and Cortes, 2016; Virtanen and Toppari, 2015). Future studies should focus on the effects of early surgery and correlate cryptorchidism etiology, once known, with long-term fertility potential.

Testicular Cancer

A history of cryptorchidism is associated with a twofold to fivefold increased risk for TGCT, or an odds ratio (OR) of 4.3 (95% CI, 3.6 to 5.1) (Banks et al., 2012; Rajpert-De Meyts et al., 2016; Schneuer, et al., 2018; Trabert et al., 2013; Wood et al., 2009). TGCT developed in 6 of 506 (1.2%) males in a cryptorchid cohort, and prior cryptorchidism is one of the most common risk factors for TGCT, composing 5% to 10% of affected individuals (Giwercman et al., 1987; Kvist et al., 2018; McGlynn and Cook, 2009). Shared risk factors include inguinal hernia, prematurity, and low birth weight (Rajpert-De Meyts et al., 2016). In a population-based study in Sweden, hypospadias (OR 2.25, 95% CI, 1.17 to 4.32), inguinal hernia (OR 1.30, 95% CI, 1.06 to 1.60), and other genital malformations (OR 1.90, 95% CI, 1.00 to 3.63) were independent risk factors for TGCT in addition to cryptorchidism (OR 3.16, 95% CI, 2.45 to 3.96) (Trabert et al., 2013). ORs were lower when cryptorchidism was diagnosed before puberty (OR 2.76, 95% CI, 2.09 to 3.65) versus after puberty (OR 4.96, 95% CI, 3.06 to 8.04), and the reverse was true for hypospadias and hernia, where associations were stronger at a younger age at presentation.

Tumors may occur in the descended testis of men with a history of unilateral cryptorchidism, as suggested by two meta-analyses showing ORs for contralateral tumor risk for 1.7 (95% CI, 1.01 to 2.98) and 1.5 (95% CI, 0.9 to 2.6) (Akre et al., 2009; Banks et al., 2012). In another meta-analysis, Walsh et al. (2007) reported an RR of 5.8 (95% CI, 1.8 to 19.3) in men undergoing orchidopexy after 10 to 11 years of age as compared with those undergoing earlier correction. Subsequent population studies have confirmed a positive correlation between age at surgery and risk, with ORs of 1.1 to 2.35 (<9 years of age), 2.9 (10 to 14 years), 5.1 (13 to 15 years), 6.2 (16 to 19 years), and 14.4 (untreated adults) (Osterballe et al., 2017). In this large series, Osterballe et al. (2017) reported the long-term outcome of a mixed population of 1403 cryptorchid males (14% syndromic) who underwent surgery at a mean age of 10.8 years, followed at a mean of 28.9 years. Among these, 16 cases of TGCT (1.1%) were identified at a mean age of 33.3 years (range 26 to 37 years of age), 8 each in cases of bilateral and unilateral cryptorchidism, with 3 arising in the contralateral scrotal testis. In the majority (81.2%) of TGCT cases, orchidopexy was performed at greater than or equal to 10 years, and 2 (12.5%) cases occurred in men with a history of syndromic cryptorchidism. In this series, 7 cases of intratubular germ cell neoplasia, unclassified (IGCNU) (0.5%) were identified prepubertally, although 4 (67%) occurred in syndromic cases, including DSD. Others have reported a prevalence of carcinoma in situ of the testis, also known as IGCNU, in 2% to 3% in previously cryptorchid men (Giwercman et al., 1989) and 0% to 0.4% of children with nonsyndromic cryptorchidism (Cortes et al., 2001; Husmann 2005). In the large population-based study of all boys born in Australia, there was also evidence of increasing risk for cancer for every 6 months delay in treatment after 18 months of age. This was similar to prior studies, although the subset of patients with cancer (27) was small (Schneuer et al., 2018).

A review of tumor pathology in treated versus untreated cryptorchidism showed that seminoma is associated with persistently cryptorchid testes (74%) and nonseminoma is present in the majority of scrotal testes (63%) (Wood et al., 2009). Both seminoma and nonseminomatous germ cell tumors (NSGCTs) arise from IGCNU. A developmental origin for TGCT, characterized by gonocytes that fail to differentiate normally and then undergo adaptive genetic and epigenetic changes to form IGCNU (Rajpert-De Meyts et al., 2016), is supported by gene expression data suggesting a common origin for the two cell types (Sonne et al., 2009). In contrast, failure of PGCs to differentiate normally may lead to infantile germ cell tumors, including teratoma/teratocarcinoma and yolk sac tumor. Although rare, these tumors have also been reported in boys with cryptorchidism before puberty (Mittal et al., 2015).

Failure of normal gonocyte differentiation in cryptorchid testes may contribute to the increased risk for IGNCU and TGCT. Markers of undifferentiated spermatogonia, including placental-like alkaline phosphatase (PLAP), octamer-binding transcription factors (OCT3/4), tyrosine kinase receptor c-KIT and its ligand, stem cell factor (SCF), homeobox nanog (NANOG), transcription factor AP2γ (TFAP2C), D2-40 receptor, and sal-like 4 (SALL4) show decreasing expression in the fetus and normally disappear after birth, but may be re-expressed in IGCNU and TGCT (Cools et al., 2005; Hoei-Hansen et al., 2005; Honecker et al., 2004; Rajpert-De Meyts et al., 2016; Stoop et al., 2008; Ulbright et al., 2014; Vigueras-Villaseñor et al., 2015) or upregulated postnatally in individuals with dysgenetic gonads at higher risk for malignancy (Rajpert-De

Meyts et al., 2004). Persistent expression of these markers beyond the first year of life in germ cells of cryptorchid testes has been reported, consistent with delayed spermatogonial maturation (Kvist et al., 2014; Thorup et al., 2013; Vigueras-Villaseñor et al., 2015). Prior evidence suggesting that expression of IGCNU markers disappears in normal testes in the first year of life (Vigueras-Villaseñor et al., 2015) was recently superseded by observations that PLAP and c-KIT expression may persist for 2 years after birth or longer, although expression of D2-40 and OCT3/4 was absent beyond 6 and 9 months, respectively (Kvist et al., 2018). Because they did not did not identify IGCNU marker expression in the majority of individuals who later developed TGCT, Osterballe et al. (2017) questioned if TGCT does in fact arise from persistent, undifferentiated gonocytes. **The persistence of gonocyte markers in cryptorchid testes is consistent with delayed spermatogonial maturation, but so far no marker can reliably predict development of IGCNU or TGCT in cryptorchidism.**

Cortes et al. (2003b) identified multinucleated spermatogonia in 13 (8%) of 163 consecutive patients undergoing biopsy at the time of orchidopexy. This occurred in younger boys and was associated with a germ cell count that was usually normal and higher than the mean for the majority of cases. Although not identified in normal boys, the relevance of this finding to tumor risk remains unknown. The risk for TGCT is higher in conditions associated with chromosomal defects or DSD (Cortes et al., 2001; Husmann, 2005). Husmann has recommended that biopsy be performed in these individuals and in boys older than 12 years of age undergoing orchidopexy, although the age cutoff and usefulness of biopsy during pubertal orchidopexy has not been clearly defined. Orchiectomy should be considered the preferred treatment of cryptorchid testes in postpubertal males up to 50 years of age (Wood et al., 2009). Swerdlow et al. (1997) reported in a retrospective cohort study that testicular biopsy at orchidopexy was associated with an increased risk for future TGCT compared with orchidopexy without biopsy (RR 6.7, 95% CI, 2.7 to 13.5), but the indications for biopsy in this series were not clearly known. A subsequent report from a large Scandinavian cohort showed that universal biopsy did not appear to increase the risk for TGCT beyond what is expected for previously cryptorchid men (Moller et al., 1998).

Testicular microlithiasis, characterized by multiple spectral calcifications within the testicular parenchyma (Fig. 46.12), is more frequently present in men with IGCNU or TGCT, but is also present in 5% to 10% of the normal population and in a similar proportion of previously cryptorchid men (Patel et al., 2005; van Casteren et al., 2009). **Although concern exists that the risk for TGCT may be higher when cryptorchidism coexists with microlithiasis in individual patients, no data exist to support this hypothesis, and the appropriate follow-up strategy remains undefined.** Even less well-defined is the significance of microlithiasis in general, which is not clearly shown to be an independent risk factor for TGCT. A population-based analysis of the prevalence of microlithiasis in a series of primarily Caucasian boys shows that the prevalence is 4.2% and increases with age (Goede et al., 2009). In about one-half of these cases, the degree of microlithiasis was limited, defined as less than 5 lesions per testis, and not considered clinically significant. The general prevalence of microlithiasis was 3.5% in boys with cryptorchidism and 6.4% in a series of 261 older boys (mean age 18.9 years) being followed up for a diagnosis of acquired cryptorchidism (Goede and Hack, 2012; van der Plas et al., 2013a). In 99 men with prior cryptorchidism, the prevalence of microlithiasis was 14% in affected testes and 19% in contralateral descended testes, with no significant difference between these groups or between cases of congenital and acquired cryptorchidism (van Brakel et al., 2015). In a recent multicenter review of over 37,000 boys, Trout et al. (2017) confirmed that a positive association exists between microlithiasis and testicular neoplasia. The prevalence of microlithiasis in this series was 2.9%. Testicular tumors were identified in 4.64% of boys with microlithiasis versus 0.33% of those without, but an association with cryptorchidism was not addressed.

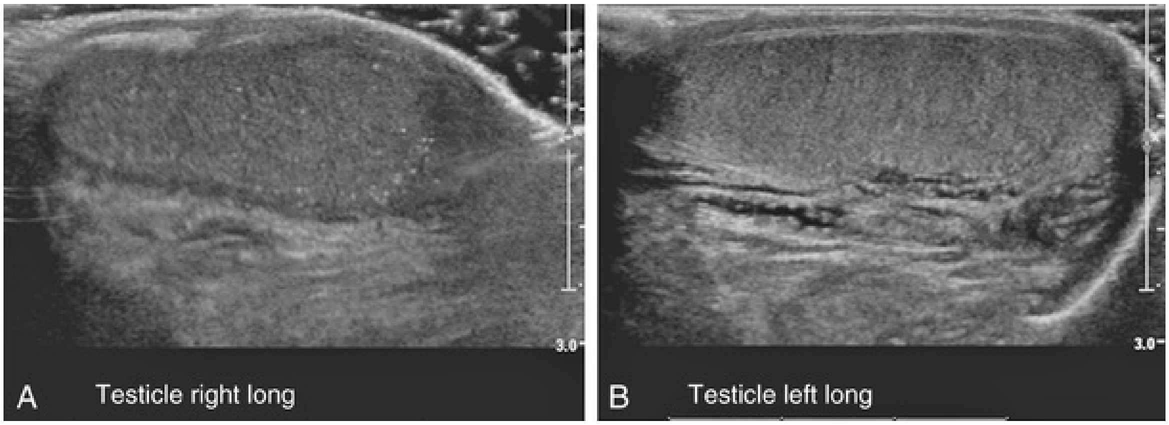

FIG. 46.12 Associated sonographic abnormalities in boys with cryptorchidism. Ultrasound images from an 11-year-old boy presenting with testicular asymmetry who underwent bilateral orchidopexies in infancy. (A) Right microlithiasis. (B) Ectasia of the left rete testis.

Other testicular abnormalities identified during ultrasound follow-up in males treated for cryptorchidism include ectasia of the rete testis (see Fig. 46.12) (Nistal et al., 1996) and intratesticular varicocele (Meij-de Vries et al., 2013). The significance of these entities in the context of cryptorchidism remains poorly defined. Routine use of ultrasonography has not been recommended.

The U.S. Preventive Services Task Force does not recommend routine testicular self-examination (TSE) in adolescents and adults, assigning it an evidence grade of “D”, in part because treatment for TGCT is highly effective, but this recommendation does not explicitly include prior cryptorchid males (http://www.uspreventiveservicestaskforce.org/uspstf10/testicular/testicuprs.htm# However, cost-benefit and other analyses suggest that recommending TSE generally is worthwhile (Aberger et al., 2014; Rovito et al., 2018). **Physicians should educate patients and their families about the risks of infertility and TGCT in cryptorchidism and provide counsel about the potential benefits of TSE.**

Key Points

- Gonadal determination involves separate genetic pathways for development of testis and ovary, and *SRY* is a master switch in males that regulates downstream testis-determining genes.
- Differentiation of gonocytes, Sertoli cells, and Leydig cells occurs between 5 and 9 weeks’ gestation, and the gubernaculum, the guide for testicular descent, appears at 7 weeks.
- Levels of the Leydig cell hormones testosterone and INSL3 peak between 14 and 17 weeks and are critical for testicular descent.
- Swelling of the gubernaculum, which starts in the second trimester, provides space for passage of the testis into the scrotum between 20 and 28 weeks.
- Cryptorchidism occurs in 1% to 4% of full-term males; both spontaneous descent (in the first few months of life, usually by 6 months) and re-ascent of testes may occur.
- The causes of cryptorchidism are largely unknown, but birth weight, gestational age, genetic factors, and environmental risk factors both likely contribute to disease risk.

- Acquired cryptorchidism is not uncommon but is likely equivalent to cases diagnosed at birth. It may occur after scrotal testes are confirmed at birth or after spontaneous descent of a cryptorchid testis and may be more common in boys with retractile testes. Yearly testicular examinations are recommended during childhood.
- About 80% of undescended testes are palpable, and 60% to 70% are unilateral.
- Epididymal anomalies and a patent processus vaginalis are common in cases of cryptorchidism.
- Subsets of boys with cryptorchidism have subtle abnormalities of the hypothalamic-pituitary-gonadal axis during mini-puberty and/or reduced levels of hormones secreted by Sertoli cells, AMH, or INHB.
- Orchidopexy is recommended for testes that remain undescended after 6 months of age; hormone therapy is not recommended.
- Laparoscopy is the procedure of choice, and imaging studies are rarely useful in the diagnosis and treatment of abdominal cryptorchidism.
- Sperm counts are reduced in at least 25% of formerly unilateral and the majority of formerly bilateral cryptorchid men, but paternity rates in the unilateral group are similar to control men.
- Ad spermatogonia counts may predict fertility potential in some males with cryptorchidism.
- TGCT risk is 2 to 5 times higher in boys with cryptorchidism and is positively correlated with age at surgery.

Management of Abnormalities of the Genitalia in Girls

Martin Kaefer MD

As with all organ systems, genital development in the female occurs in an orderly fashion through multiple complex steps that result in an anatomically and functionally normal child in the majority of cases. However, errors in development can occur, from minor, clinically insignificant disorders to severe abnormalities that are devastating to the child and parents. The abnormalities can be seen alone or in combination with internal genital anomalies or be a part of a more global syndrome that involves many organ systems. This chapter briefly describes normal female urogenital development and then discusses anomalies that arise when abnormal development occurs. Genital ambiguity may be the initial finding in these disorders.

Female Genital Embryology

A comprehensive description of genitourinary embryology can be found in other chapters. However, to foster a deeper understanding of the complex combination of anomalies that can occur in patients with external genital/vaginal anomalies, a brief review of relevant embryologic events is presented.

The cloaca is an endoderm-lined primordial organ that is first apparent at the beginning of the second week of gestation (Grosfeld, 1996). This structure, which represents a confluence of the primitive hindgut (dorsally) and the allantois (ventrally), receives the mesonephric ductal system just before the fourth week of gestation. The urorectal septum, which first appears during the fourth week of development, separates the urogenital sinus (ventrally) from the anal canal (dorsally) (Moore and Persaud, 1995). The urorectal septum actually consists of two components. The first is the Tourneux fold, which develops along the coronal plane in the angle between the allantois and the hindgut and grows in a caudal fashion toward the cloacal membrane. As this septum nears the cloacal membrane, infoldings of the lateral walls of the cloaca form Rathke plicae, which coalesce in the coronal midline and form the urorectal septum caudally. By weeks 6 to 7 of development the urorectal septum has fused with the cloacal membrane and divided it into a ventral urogenital membrane and a dorsal anal membrane. The fibromuscular node of tissue that results from contact of the septum with the cloacal membrane serves as a critical insertion site for the perineal muscles and as the dividing point of the primitive cloacal sphincter complex into anterior (urogenital diaphragm) and posterior (external anal sphincter) components. **The common ontogeny of these two sphincter complexes explains why the pudendal nerve supplies all of these muscles.**

While the urorectal anlage is undergoing division, the developing mesonephric ducts, which have contacted the cloaca, enter the urogenital sinus near the müllerian tubercle (Churchill et al., 1978). An offshoot of the mesonephric duct, the ureteric bud, extends cranially to induce development of the metanephric blastema, the mass of cells that will form the secretory component of the kidney. The terminal branch point of the ureteral bud from the mesonephric duct is later absorbed into the wall of the urogenital sinus. Proper incorporation of this complex results in the ureters opening at the lateral aspect of the trigone.

During this critical phase of development, paired müllerian ducts, which

form from the coelomic epithelium, develop lateral to the mesonephric ducts and cross medially to fuse in the midline. The close proximity of these two ductal systems helps explain the common association of paramesonephric abnormalities and ipsilateral renal anomalies. The paired müllerian ducts then proceed caudally to join the urogenital sinus, where they produce an elevation called the *müllerian tubercle*. The caudal fusion of portions of these ducts normally leads to dissolution of the shared midline partition and the formation of a common uterovaginal canal, which, as the name implies, gives rise to the uterus, cervix, and proximal two-thirds of the vagina. Failure of septal regression can result in a number of possible müllerian duct abnormalities.

As first delineated by Koff in 1933, contact of the uterovaginal primordium with the urogenital sinus forms the müllerian tubercle, which in turn induces the formation of paired caudal endodermal outgrowths called *sinovaginal bulbs*. Evidence suggests that these outpouchings may in fact represent the terminal segments of the wolffian ducts (Bok and Drews, 1983). Regardless of origin, the cells within these sinovaginal bulbs then proliferate to form a cord of tissue that develops into a distal vaginal plate, which is later canalized in a caudal-to-cranial direction to form the distal aspect of the vagina (Fig. 47.1). The portion of the urogenital sinus distal to the müllerian tubercle subsequently undergoes exstrophy and everts to become the vestibule. As a result of this process, the urethra and vagina acquire separate openings in the vulva. The lumen of the vagina is separated from the cavity of the urogenital sinus by the hymen, an invagination of the posterior wall of the urogenital sinus. Rupture of the hymen should occur during the perinatal period.

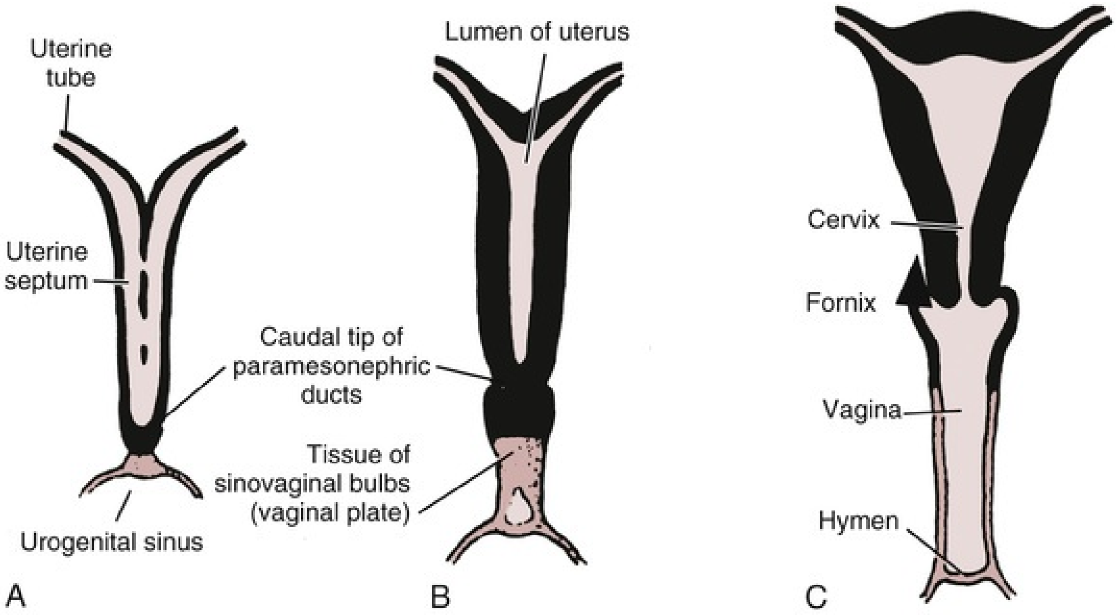

FIG. 47.1 (A to C) Formation of the vagina from the sinovaginal bulbs. (From Saler TW: *Langman's medical embryology,* ed 6, Baltimore, 1990, Williams & Wilkins.)

Various cystic structures may form along the luminal aspect of the vagina. Remnants of the prostatic ductal system and the wolffian duct give rise to the paraurethral glands of Skene and Gardner, respectively. Outgrowths from the urogenital sinus form the greater vestibular glands of Bartholin, which are homologs of the bulbourethral glands in the male.

Key events in skeletal formation occur concurrently with cloacal division and proper formation of the mesonephric and paramesonephric ductal systems (Churchill et al., 1978). The vertebrae develop in a craniocaudal direction, with the lower extremity limb buds developing from condensation of somites 25 through 29. These somites undergo critical differentiation from the fourth through the eighth weeks of development.

From the foregoing brief description of caudal embryology it should be evident that a disturbance in segmentation at the level of the caudal somites when the fetus is less than 10 mm (fourth to fifth weeks of human development) can affect many organ systems. Duhamel (1961) described the association of these “coincidentally” occurring congenital malformations and introduced the term *caudal regression syndrome*. Laboratory data with teratogens support the concept that a key event occurs between the fourth and fifth weeks of gestation that results in an error in the simultaneous development of the terminal bowel, kidney, bladder, paramesonephric ductal system, and lumbosacral spine (Mesrobian et al., 1994). The actual inciting event remains unclear, although disordered mesodermal migration, reduced cellular proliferation, and premature apoptosis have been proposed as potential mechanisms (Alles and Sulik, 1993; Kallen and Winberg, 1974). Elements of the caudal regression syndrome are seen with increased frequency in infants of mothers with diabetes, but the exact mechanism is still in question (Deuchar, 1978; Lynch et al., 1995). Specific gene deletions in the homeobox region of the mammalian genome (the region critical for proper mammalian spatial orientation and segmentation) have been shown to result in a constellation of anatomic findings, as predicted by Duhamel (Warot et al., 1997). Because differentiation of the somites progresses in a cranial-to-caudal direction, it would follow that the most complex anomalies (higher anorectal malformations) would occur as a result of aberrations at an earlier stage of development. This also helps explain the greater association of severe upper urinary tract malformations, internal genital duct abnormalities, and spinal anomalies in these patients than in those with less severe cases of imperforate anus.

Mesodermal disturbances are not limited to the caudal somites. As seen in the VATER (***V***ertebral defects, ***A***nal atresia, ***T***racheoesophageal fistula with ***E***sophageal atresia, and ***R***adial and **r**enal dysplasia) and MURCS (***MÜ***llerian duct aplasia, ***R***enal aplasia, and ***C***ervicothoracic ***S***omite **d**ysplasia) associations, mesodermally derived organs as cranial as the C1 vertebra and tracheoesophageal anlagen can be affected in association with congenital abnormalities of the mesonephric and paramesonephric ductal systems (Duncan et al., 1979; Quan and Smith, 1973).

Key Points: Female Genital Embryology

- The common ontogeny of the urogenital sphincter and the external anal sphincter explains why the pudendal nerve supplies both muscle complexes.
- The close proximity of the müllerian and wolffian ductal systems is responsible for the common association of paramesonephric abnormalities and ipsilateral renal anomalies.
- A disturbance in segmentation at the level of the caudal somites during the fourth or fifth weeks of development can result in a constellation of

malformations involving the urogenital, skeletal, and gastrointestinal systems that are commonly referred to as the *caudal regression syndrome*.

Evaluation and Classification of Female Genital Anomalies

Structural anomalies of the vulva are numerous and varied. The differential diagnosis in the neonate and young child is broad and requires a thorough understanding of the diagnostic possibilities and a systematic evaluation. The age and racial background of the patient can help narrow the differential diagnosis, but physical examination remains the most useful tool for determining the specific pathology.

The physician must be sure to specifically reassure the girl that the examination will not be painful. With the child in the frog-leg position, the physician should note the size of the clitoris, the configuration of the hymen, the location of the urethra, and the character of the interlabial mass (e.g., smooth, lobulated, hemorrhagic). **To aid in visualization, the labia majora can be gently grasped and pulled caudally and laterally to enable funneling of the introitus and vagina (often referred to as the "pull-down maneuver")** (Kaefer, 2010; Fig. 47.2). Establishing the location of expected anatomic landmarks can facilitate determining the nature of a specific mass. In certain circumstances, the relationship of the mass to the vagina and urethra can be improved by gentle placement of a lubricated cotton applicator posteriorly or placement of a small feeding tube within the suspected urethral orifice, or both. Although an otoscope, nasal speculum, or pediatric vaginal speculum can be useful in evaluating the vagina while the patient is awake, complaints of vaginal origin (i.e., vaginal discharge or bleeding) are often best investigated with a carefully performed examination and vaginoscopy under anesthesia. Renal-pelvic ultrasonography can be a useful adjunct in confirming or establishing the diagnosis in a few of these disorders.

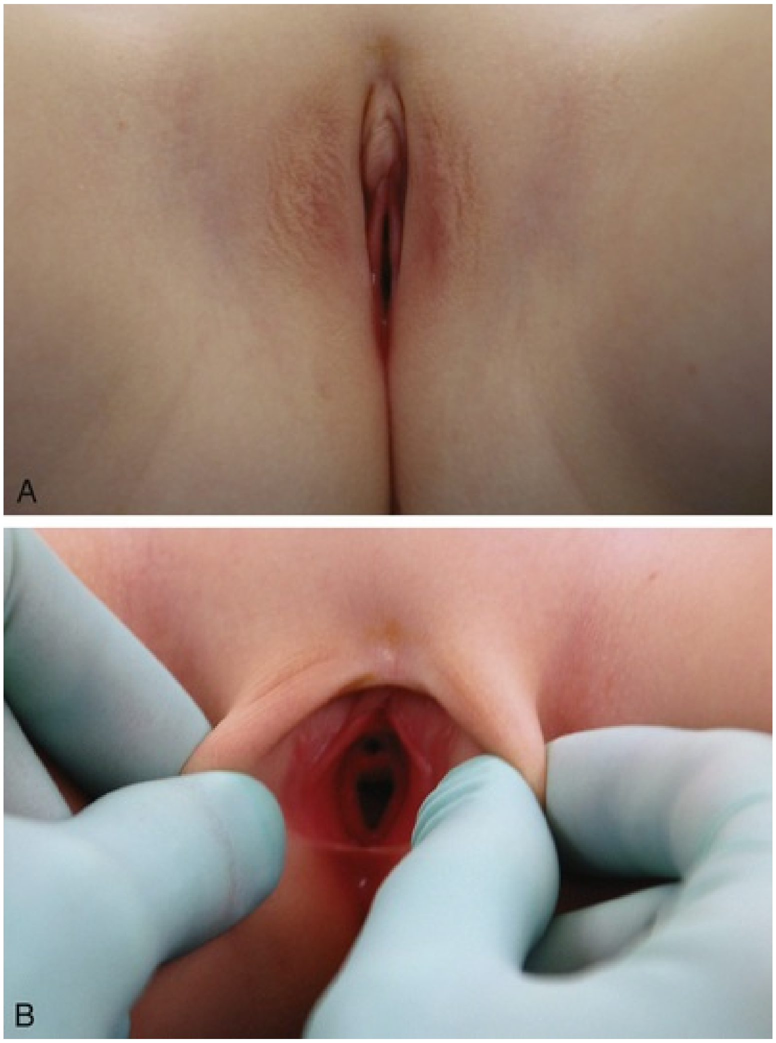

FIG. 47.2 (A and B) Photographs of the labial "pull-down maneuver." To aid in visualization of the female introitus, the labia majora are gently grasped and pulled caudally and laterally to enable funneling of the introitus and a clear view of the distal vagina.

Structural anomalies of the vagina can be grouped into three main categories: (1) those resulting from either hypoplasia or agenesis, (2) those caused by vertical fusion (canalization abnormalities resulting from abnormal contact of the müllerian structures with the urogenital sinus), and (3) those resulting from lateral fusion (duplication). The clinical manifestations, physical findings, evaluation, and subsequent therapy vary considerably among these groups. Radiographic imaging is of central importance in determining the correct diagnosis. Ultrasonography is helpful not only in identifying the genital anatomy but also in screening for associated upper urinary tract abnormalities (Fernandez et al., 1996; Rosenberg et al., 1986). Magnetic resonance imaging (MRI) is considered by many to be the gold standard for defining müllerian anatomy (Fedele et al., 1996; Lang et al., 1999; Russ et al., 1997). It is especially useful for determining the presence or absence of the cervix and the presence of functioning endometrium in complex anomalies. In complicated cases, additional information can be obtained by examination under anesthesia, vaginoscopy, hysteroscopy, and laparoscopy (Major et al., 1997). Obstructive anomalies typically require immediate intervention, but nonobstructive anomalies often do not require surgical intervention unless the patient has reached reproductive age and the condition affects intercourse or adversely affects fertility. Various systems have been proposed for the classification of these anomalies, with the system proposed by the American Society for Reproductive Medicine being the most inclusive (American Fertility Society, 1988).

Congenital Disorders of Female External Genitalia

Disorders of the Clitoris

Hypertrophied Clitoris

Clitoral hypertrophy is most commonly the result of excess androgenic metabolites arising secondary to an enzymatic defect in adrenal steroid synthesis (Fig. 47.3). The most commonly seen syndromes of congenital adrenal hyperplasia (CAH) result from a deficiency of either 21-hydroxlase or 11-hydroxylase. Some degree of clitoral enlargement can be appreciated in nearly every female patient with CAH. Although there is often concordance between the degree of clitoromegaly and the length of the common urogenital sinus, this does not always apply. Because the overwhelming majority of clitoral hypertrophy is secondary to CAH, any newborns noted to have this physical finding should undergo an evaluation of their serum electrolytes, 17-hydroxyprogesterone level, and karyotype. Replacement of glucocorticoids and mineralocorticoids will exert a negative feedback on the adrenal gland and thus eliminate further stimulation of the external genitalia from endogenously derived androgens. Medical and surgical management of this disorder is discussed elsewhere in this text.

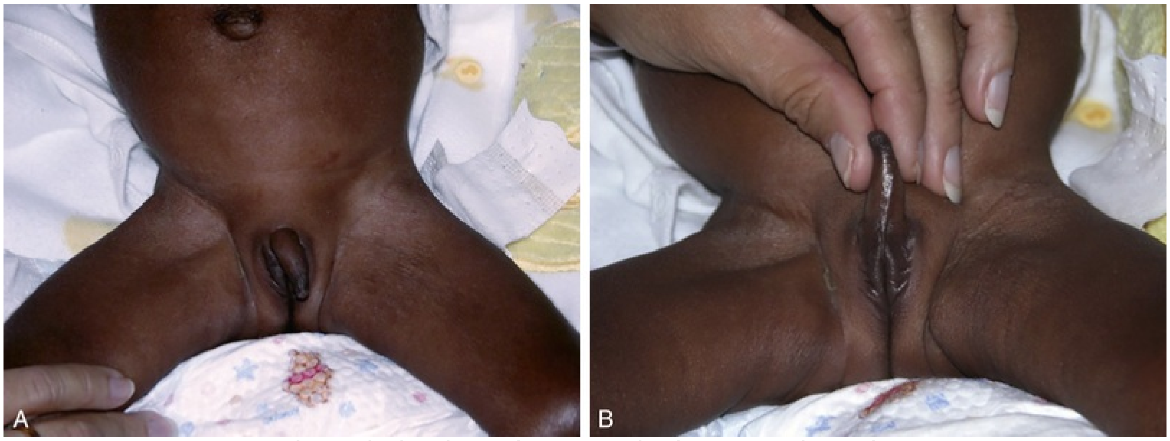

FIG. 47.3 (A and B) Clitoral hypertrophy in congenital adrenal hyperplasia.

Clitoral enlargement can result from other disorders. Endogenous androgen-producing tumors in the mother can result in stimulation of the fetal phallus. The presence of unilateral viable testicular tissue in a patient with Turner syndrome also has been reported (Haddad et al., 2003). Finally, local growth factor secretion from a neighboring plexiform neurofibroma in patients with neurofibromatosis has been reported on multiple occasions to result in clitoromegaly (Cost et al., 2009; Kaefer et al., 1997; Kearse and Ritchey, 1993; Rink and Mitchell, 1983; Yuksel et al., 2003).

Diminutive Clitoris

Small clitoral size (Fig. 47.4) is found in patients with complete androgen insensitivity syndrome (CAIS). One study evaluating 19 patients with known CAIS revealed a statistically significantly reduced mean clitoral length compared with that in controls (Crouch et al., 2011). In contrast, no difference was observed for the clitoral to urethral distance between the two groups.

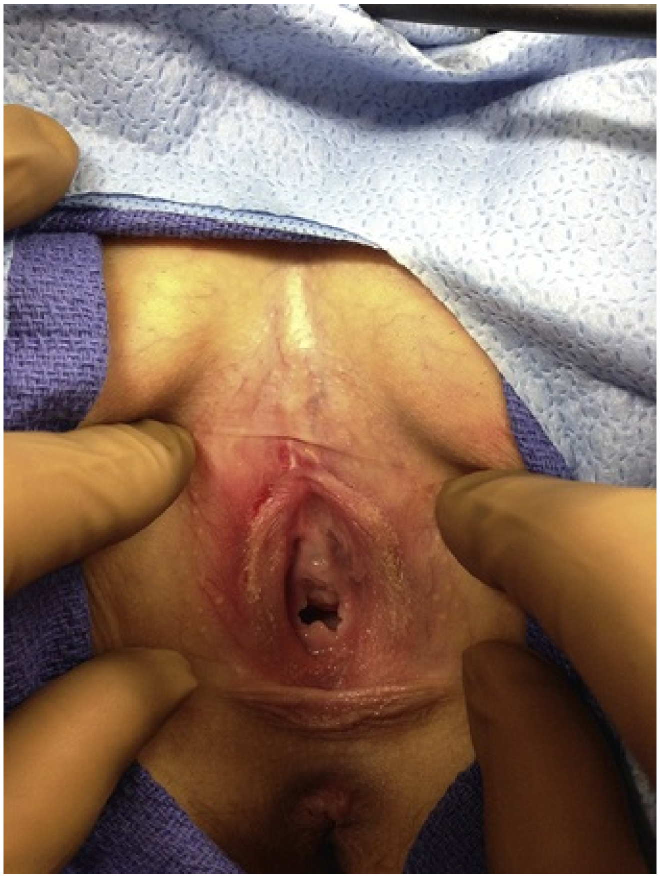

FIG. 47.4 Diminutive clitoris in complete androgen insensitivity syndrome.

Disorders of the Vestibule

Urethral Prolapse

Urethral prolapse generally involves complete circumferential eversion of the urethral mucosa at the level of the external urethral meatus (Fig. 47.5; Lowe et al., 1986). **This entity, first described by Solinger in 1732, occurs most often in prepubertal black girls and in postmenopausal white women** (Epstein and Strauss, 1937; Richardson et al., 1982). Various causes that have been proposed for urethral prolapse include hypoestrogenism (Desai and Cohen, 1997), abnormal connections between the inner longitudinal and outer circular muscle layers of the distal urethra (Lowe et al., 1986), and episodic increases in intra-abdominal pressure (Desai and Cohen, 1997; Lowe et al., 1986; Valerie et al., 1999). The most common initial complaint is bleeding from the edematous and friable mucosa, which results in blood spotting on the underwear (Chaouachi et al., 1989; Richardson et al., 1982). Urethral prolapse is easily recognized as a doughnut-shaped mass with the urethral meatus at the center. If the diagnosis can be confirmed by passing a urethral catheter, radiographic evaluation is not indicated (Nussbaum and Lebowitz, 1983). Treatment options include observation, topical corticosteroids, conjugated estrogens, and surgical excision (Fernandes et al., 1993; McCaskill et al., 2018; Redman, 1982). Sitz baths may be helpful. **Nonoperative treatment may lead to spontaneous reduction of the prolapse, but a recurrence rate of up to 67% has been noted** (Jerkins et al., 1984). Many methods of surgical repair have been described. Circumferential excision of the redundant mucosa with subsequent suturing of the normal urethra to the vestibule is the procedure of choice (Devine and Kessel, 1980). Other methods, including ligation over a transurethral catheter with subsequent sloughing and cryosurgery, should be discouraged (Klaus and Stein, 1973; Owens and Morse, 1968).

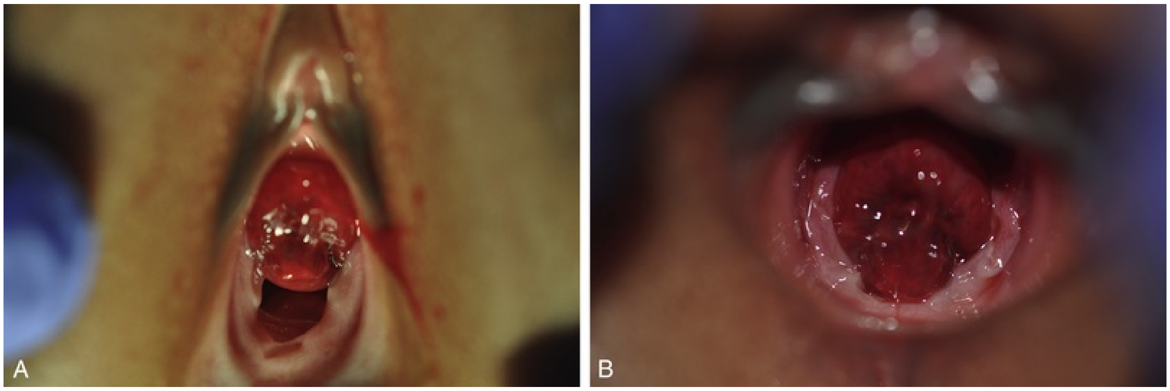

FIG. 47.5 (A and B) Urethral prolapse.

Urethral Polyp

The pediatric equivalent of a urethral caruncle, namely, a urethral polyp, is a rare lesion that can manifest as an interlabial mass (Fig. 47.6). The cause of these lesions has not been completely elucidated, but in a young child they probably represent either hamartomatous growth or a response to inflammation.

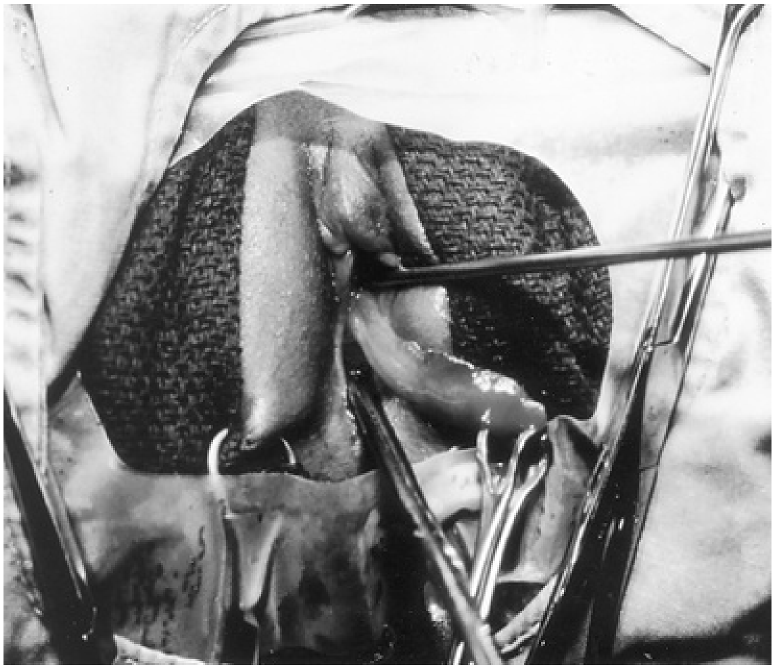

FIG. 47.6 Urethral polyp. Probe in urethra and Babcock clamp on urethral polyp.

Klee described two young girls with an interlabial mass. Histologic examination of each excised mass revealed a benign urethral polyp covered with transitional and squamous epithelium (Klee et al., 1993). Urethral polyps should be included in the differential diagnosis of an interlabial mass in young female patients.

Vestibular Cysts

Introital cysts in the newborn can represent one of three entities: paraurethral cysts (i.e., Skene duct cyst), remnants of the mesonephric ductal system (Gartner duct cyst), and a covered ectopic ureter. When the cyst is large and clearly emanating from the vaginal introitus, further investigation in the form of a renal-pelvic ultrasound evaluation is indicated to look for renal duplication.

Paraurethral cysts in a neonate represent a dilation of the periurethral glands, which are located just inside the urethral meatus (Fig. 47.7). These glands are homologs of the male prostatic glands and number between 6 and 30, with the two largest termed the *periurethral glands of Skene* (Gottesman and Sparkuhl, 1979; Skene, 1880). In a neonate the periurethral glands occasionally respond to maternal estrogen and secrete mucoid material, which can result in cyst formation. The main distinguishing feature of this condition is displacement of the urethral meatus by the mass and, consequently, an eccentric urinary stream. If the urethral meatus can be identified as being completely separate from the mass, radiographic evaluation is not needed to confirm the diagnosis (Nussbaum and Lebowitz, 1983). These cysts are frequently self-limited and often rupture spontaneously. If they are persistent, drainage by a small needle is easily achieved at the bedside.

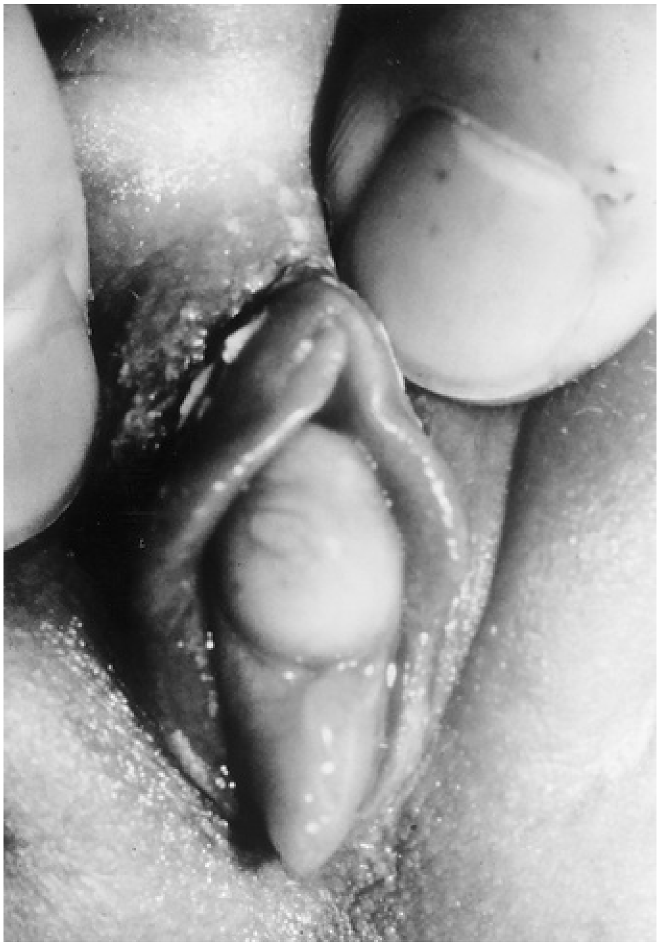

FIG. 47.7 Paraurethral cyst.

Gartner duct cysts represent incomplete regression of the wolffian duct system. They are cystic remnants that can be found along the anteromedial wall of the vagina (Pradhan and Tobon, 1986). A cystic structure related to a Gartner duct cyst is a covered ectopic ureter that enters into the vagina (Holmes et al., 1999; Rosenfeld and Lis, 1993). Embryologically, the ureter would not be expected to enter the vagina. However, an ectopically located ureter may end in a segment of the wolffian duct system, which in a female is represented by a Gartner duct cyst. In most instances this cystic structure spontaneously ruptures before delivery, thereby resulting in direct communication between the ectopic ureter and the vagina. However, if the surface epithelium fails to rupture, a covered, urine-filled cyst will exist within the vagina. Intraoperative injection of the cystic structure with radiographic contrast material may be beneficial in outlining the anatomy (Fig. 47.8). Incision of the cystic structure relieves the obstruction. As a general rule, the more ectopic the insertion of the ureter, the more dysplastic will be the segment that it drains. However, renal moieties that ectopically insert into the vagina may produce urine. Subsequent upper pole heminephrectomy may be indicated if the child has significant urine production from the segment (resulting in incontinence) or an infection develops after decompression.

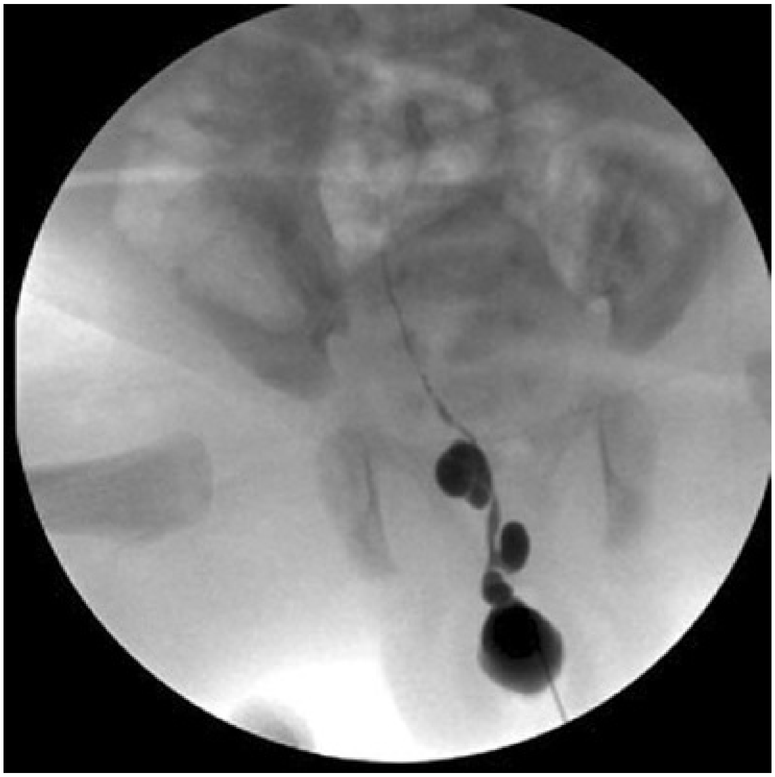

FIG. 47.8 Retrograde injection of an ectopic ureter inserting into a Gartner duct cyst. After injection of a vaginal cyst, contrast agent ascends cranially into an atretic, dysplastic ureter.

Prolapsed Ureterocele

An ectopic ureterocele is a cystic dilation of the terminal portion of the ureter that occurs predominantly in white females (Mandell et al., 1980). Approximately 90% of ectopic ureteroceles are associated with the upper pole of a duplex collecting system. Although they normally remain positioned proximal to the bladder neck, some may prolapse through the urethra during micturition, almost always in infancy, and result in urinary retention and a relative urologic emergency (Gingell et al., 1971). **Depending on the length of time that the ureterocele has been prolapsed, it may vary in color from pink to dusky purple (Fig. 47.9). If a prolapsed ureterocele is in the differential diagnosis,** bladder-renal ultrasonography should be performed to look for upper pole hydronephrosis in a duplicated collecting system (Fig. 47.10).

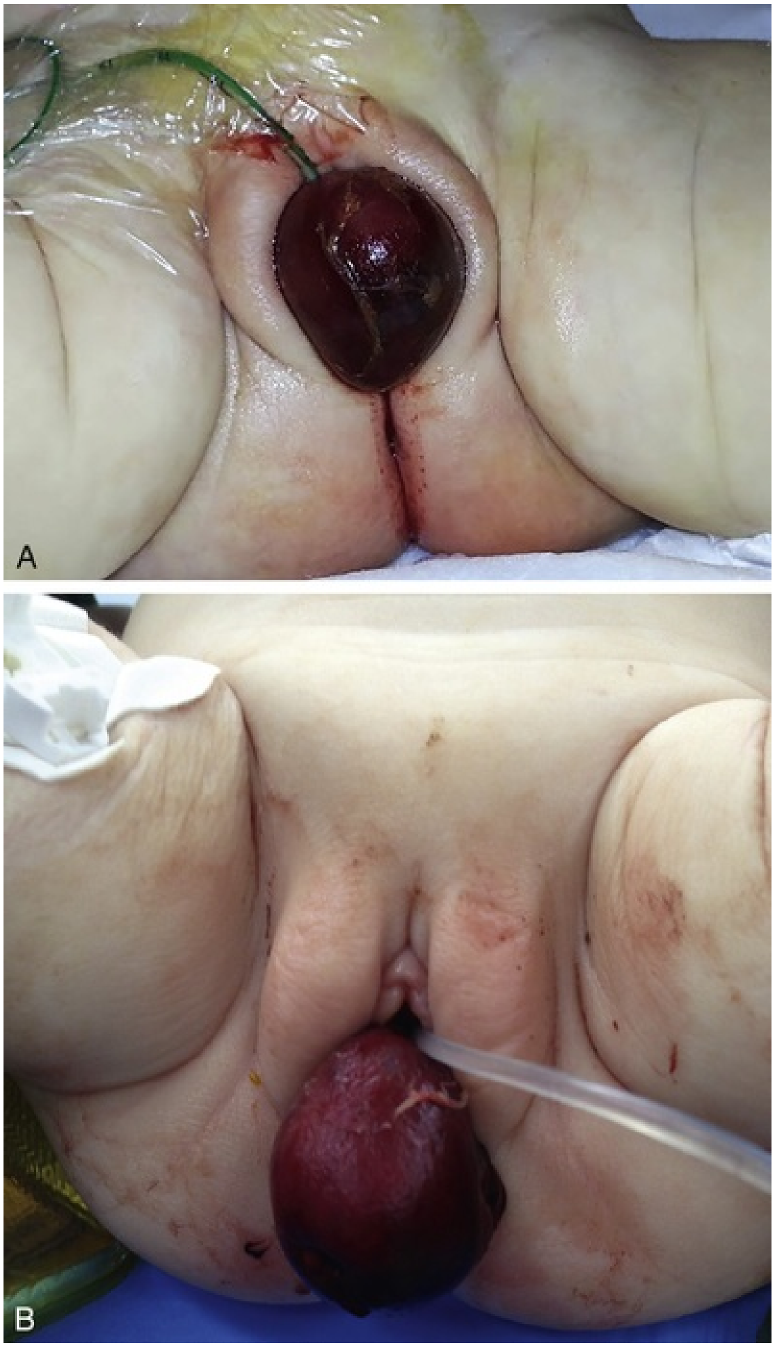

FIG. 47.9 (A) Prolapsed ureterocele. (B) Prolapsed ureterocele with catheter inserted in the urethra.

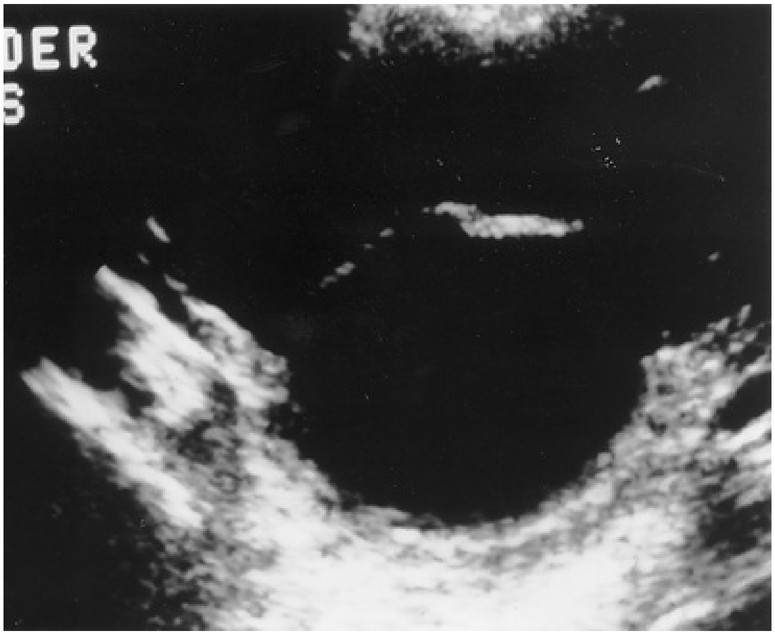

FIG. 47.10 A ureterocele evident on ultrasonography of the bladder.

Treatment of a prolapsed ureterocele consists of either needle decompression or incision and reduction and then placement of a urethral catheter. Although this occasionally can be achieved in the emergency department setting, abdominal straining by the infant may make this procedure difficult, and treatment under general anesthesia often is preferable. Injection of radiographic contrast material into the ureterocele can be helpful in identifying the relevant anatomy.

Ectopic Ureteral Insertion

In females an ectopic ureter may enter distal to the urethral sphincter. Ectopic ureters to the vestibule are typically associated with diurnal incontinence in the presence of normal voiding habits (Fig. 47.11). Most commonly the ureter subtends an upper pole of a duplex system. However, single-system ectopic ureters also may manifest in this fashion and on occasion can be associated with apparent complete absence of the kidney. A thorough search for an ectopic kidney at times may prove fruitful in identifying the cause of the patient's wetting (Borer et al., 1998).

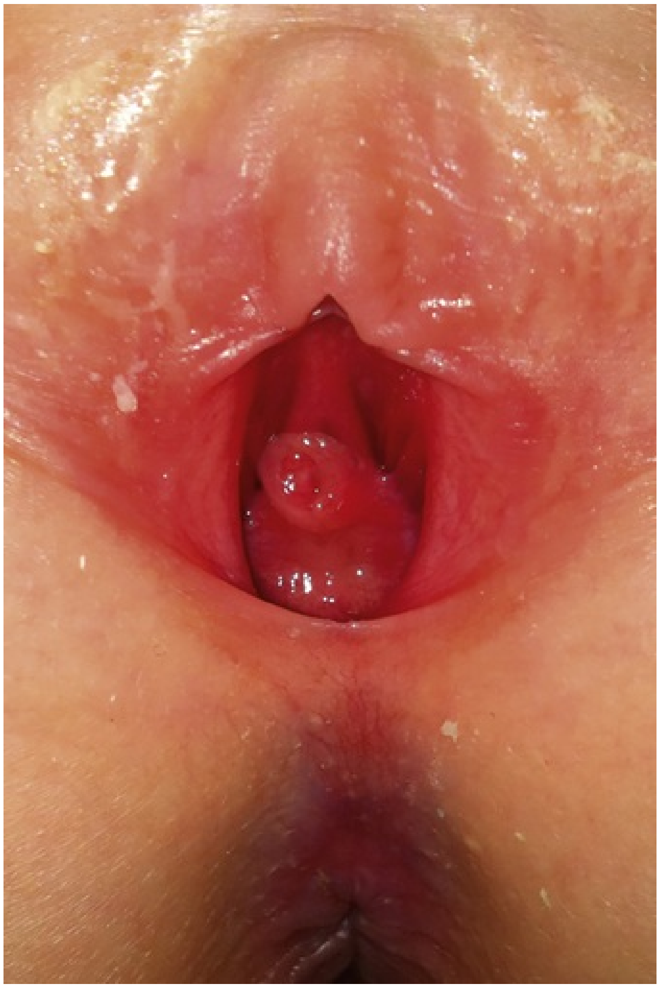

FIG. 47.11 Ectopic ureter to vestibule.

Key Points: Disorders of the Clitoris, Vestibule, and Urethra

- A diminutive clitoris is seen in patients with CAIS.
- Workup for a child with an introital (interlabial) mass that appears to be associated with the urethra always should include renal-pelvic ultrasonography.
- Urethral prolapse occurs most often in prepubertal black girls and in postmenopausal white women.

Disorders of the Vagina

Imperforate Hymen and Hymenal Skin Tags

Hymenal skin tags are almost a normal finding and are rarely symptomatic (Fig. 47.12). When symptomatic (i.e., bleeding), they should be excised to ensure that they do not represent a malignancy and to provide symptomatic relief. Congenital abnormalities of the hymen are not uncommon and range from an imperforate hymen to one with numerous small microperforations.

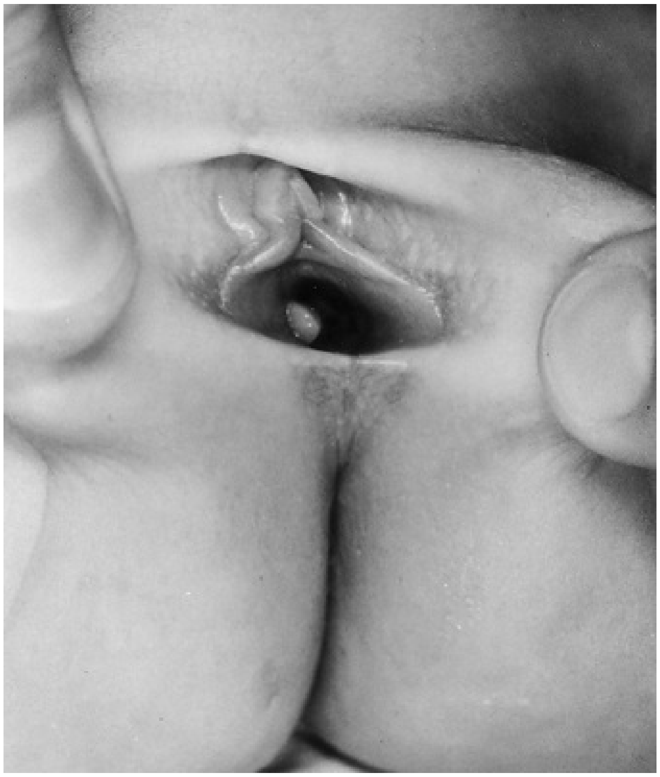

FIG. 47.12 Hymenal skin tag.

Imperforate hymen is probably the most common congenital obstructive anomaly of the female reproductive tract. The diagnosis is most frequently made at birth by noting the presence of a bulge along the posterior aspect of the introitus, which represents retained fluid within the vagina, or by palpation of a suprapubic mass from a distended vagina (Fig. 47.13). The buildup of retained vaginal secretions in the neonatal period, which imparts a whitish appearance to the bulging hymenal membrane, is caused by maternal estradiol stimulation. If the diagnosis is made after the neonatal period, the mucus often will have been reabsorbed, and a bulge in the hymenal membrane may no longer be evident. On occasion, the diagnosis is not made until the adolescent period, when the patient experiences amenorrhea and possibly cyclic abdominal pain. In these circumstances, a bluish bulging hymen may be observed on genital inspection and a mass will be appreciated on rectoabdominal palpation. In newborns, repair by incision of the hymenal tissue at the bedside is performed in the transverse direction to avoid inadvertent extension of the incision anteriorly or posteriorly (which may injure the urethra or rectal structures). Simple aspiration of the vagina without a definite drainage procedure should be discouraged because incompletely evacuated material may be prone to ascending bacterial growth. In pubertal girls, general anesthesia with excision of excess hymenal tissue may be indicated (Fig. 47.14).

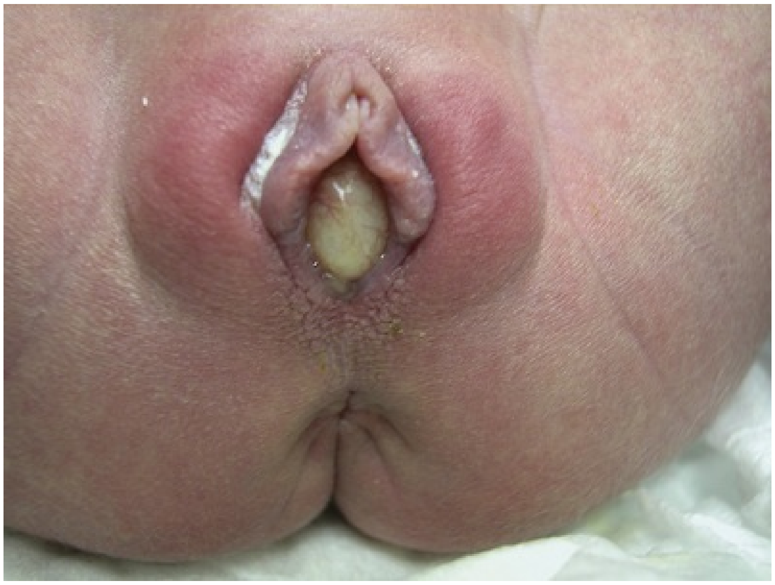

FIG. 47.13 Imperforate hymen. Note the significant distention from vaginal secretions.

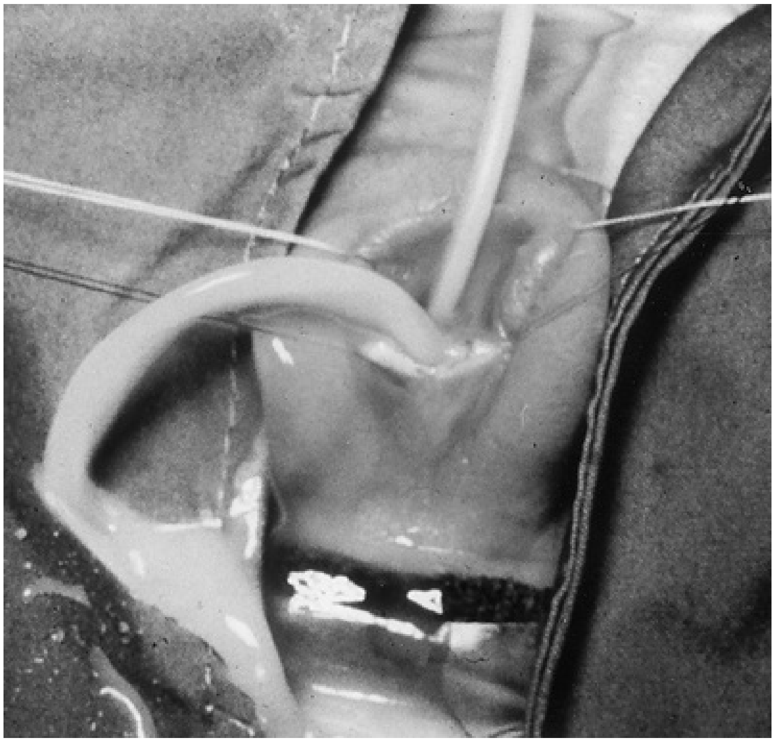

FIG. 47.14 Intraoperative photograph showing incisional drainage of an imperforate hymen. (From Yerkes EB, Rink RC: What urologists should know about pediatric gynecologic abnormalities. *Contemp Urol* 14:12, 2002.)

Acquired abnormalities of the hymenal ring usually result from sexual abuse. The associated finding of a hematoma, abrasion, or laceration in combination with hymenal transection should raise the possibility of this diagnosis. Proper examination under anesthesia and forensic swabbing of affected areas should be undertaken with the use of a standardized protocol.

Abnormalities of Vertical Fusion

General.

Patients with vertical fusion anomalies typically experience amenorrhea and abdominopelvic pain after the initiation of puberty. It is common for these patients to experience abdominal distention resembling a pregnancy. Awareness of this condition is important to avoid delay in diagnosis. A delay in diagnosis can increase the probability of retrograde menstrual flow through the fallopian tubes with resultant endometriosis (Deligeoroglou et al., 2012).

Transverse Vaginal Septum.

Transverse vaginal septa are believed to arise from a failure in fusion or canalization (or both) of the urogenital sinus and müllerian ducts. The estimated incidence of transverse vaginal septum is 1 in 70,000 females (Banerjee and Laufer, 1998). Many of the patients have amenorrhea and a distended upper vagina and experience amenorrhea. However, the condition may be incidentally recognized on imaging obtained for other reasons. **A complete transverse vaginal septum may be located at various levels in the vagina, but there is a higher frequency in the middle and upper third of the vagina. In one large series the distribution was 46% in the upper vagina, 40% in the middle vagina, and 14% in the lower vagina** (Fig. 47.15; Lodi, 1951). The septa are usually less than 1 cm thick and frequently have a small central or eccentric perforation (Suidan and Azoury, 1979). Even in cases in which a perforation is present, significant obstruction and ascending infection can occur. Transperineal, transrectal, and abdominal ultrasonography and MRI may be beneficial in establishing the diagnosis and determining the location and thickness of a transverse vaginal septum (Ammann et al., 1983; Caloia et al., 1998; Doyle, 1992; Fedele et al., 1999; Lang et al., 1999; Meyer et al., 1995). MRI can help determine whether a cervix is present so that a high septum can be differentiated from congenital absence of the cervix. Failure to differentiate between these diagnoses can result in significant patient morbidity (Casey and Laufer, 1997).

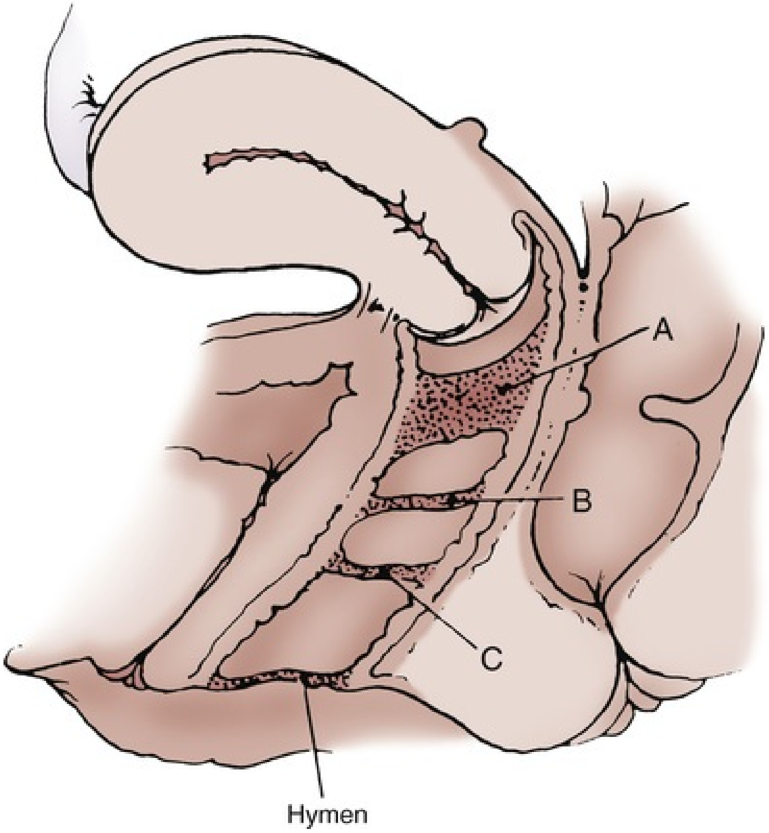

FIG. 47.15 Transverse vaginal septum. *A,* High (upper vagina); *B,* middle; *C,* low.

Several surgical treatment modalities have been developed to treat congenital transverse vaginal septa. If the patient's pain from hematocolpos is manageable, surgery may be delayed with suppression of endometrial activity by a gonadotropin-releasing hormone (GnRH) agonist or continuous oral contraceptives (Beyth et al., 2004). This may allow time for dilation of the lower vaginal segment, potentially improving the ease of surgical repair. Techniques include simple incision (Brenne et al., 1965; Buttram, 1983), surgical excision of the septum followed by approximation of the corresponding portions of the transversely cut edges of the upper and lower mucosal membranes of the septum (Rock et al., 1982), and the use of Z-plasties involving vaginal mucosa (Wierrani et al., 2003). We have described a method that improves the safety of entering the obstructed vaginal segment and subsequently excising the septum (Keenan and Kaefer, 2012). Under ultrasound guidance a 14-gauge angiocatheter is placed through the thick transverse septum. After aspiration reveals thick blood, a 0.35-mm Sensor wire (Boston Scientific, Marlborough, MA) is placed through the angiocatheter and the NephroMax (Boston Scientific) balloon dilating system is placed over the wire. The balloon is insufflated and subsequently removed, providing a generous aperture through which the remainder of the septum can be excised (Fig. 47.16). In cases in which the septum is of significant thickness, subsequent excision of the wall with a resectoscope loop can provide a more satisfactory long-term result.

FIG. 47.16 Balloon-assisted division of transverse vaginal septum. (A) Hematocolpos on magnetic resonance imaging resulting from transverse vaginal septum. (B) Angiocatheter placed into transverse vaginal septum (placed under ultrasound guidance). (C) NephroMax balloon dilating the septum.

A transabdominal surgical approach for management of transverse vaginal septum has been described. The posterior wall of the distended vagina is opened in a vertical fashion to reveal the septum, which is then perforated. An inflated Foley balloon is left across the site for 2 weeks and then removed. Although this approach would seem unnecessarily cumbersome, the authors suggest this as an alternative approach when sociocultural beliefs dictate that the hymen is not violated (Gezginc et al., 2011).

Vaginal stenosis at the site of resection is the most common complication (Joki-Erkkila and Heinonen, 2003). To minimize this complication Z-plasties are often used. The primary advantage of a Z-plasty is that as the suture line contracts the incision is more likely to take on a longitudinal rather than a transverse orientation. Placement of a vaginal mold subsequent to surgery has been reported to further reduce the risk for postoperative stenosis (Bijsterveldt and Willemsen, 2009). Characteristics of molds for transverse septa are different from those used after a McIndoe vaginoplasty (see later). Whereas a solid mold may be used after a vaginoplasty skin graft (because there is no uterus), the mold used after resection of a transverse septum is ideally hollow, to allow egress of menstrual flow.

Vaginal Atresia (Distal Vagina).

Vaginal atresia occurs when the urogenital sinus fails to contribute to formation of the lower (distal) portion of the vagina. This condition differs from vaginal agenesis and testicular feminization in that the müllerian structures are not affected. As a result, the uterus, cervix, and upper portion of the vagina are normal. A very shallow dimple caudal to the urethral opening may be appreciated on physical examination. Palpation of a distended vagina on rectal examination may help distinguish this condition from testicular feminization or vaginal agenesis. Radiographic evaluation in the form of ultrasonography or MRI, or both, is mandatory to adequately define the müllerian anatomy before intervention.

Surgical correction consists of a transverse incision at the level of the hymenal ring. Dissection is carried out through the fibrous area of the absent lower vagina until the upper vagina is reached. As in treatment of a transverse vaginal septum, distention of the vagina with retained menstrual blood products can prove extremely beneficial in that it acts as a tissue expander. After the obstruction is drained and the vaginal mucosa is identified, a pull-through procedure can be performed to bring the distended vagina down to the introitus. The distance to bridge between the vagina and the perineal surface almost always can be successfully managed with perineal skin flaps or simple mobilization of the vagina (or both). Ramenofsky and Raffensperger (1971) described a combined abdominoperineal approach that can help in exposing and anastomosing the distal vagina to the perineal skin.

Vaginal Agenesis (Müllerian Aplasia).

Vaginal agenesis, which occurs at an incidence of approximately 1 in 5000 live female births, is congenital absence of the proximal portion of the vagina in an otherwise phenotypically (i.e., normal secondary sexual characteristics), chromosomally (i.e., 46,XX), and hormonally (i.e., normal levels of luteinizing hormone and follicle-stimulating hormone) intact female (Bryan et al., 1949; Griffin et al., 1976; Herlin et al., 2016). Although Renaldus Columbus is credited by some authors as the first to describe a case of vaginal agenesis, Mayer (1829) was one of the first to report vaginal agenesis in stillborn children (Lesavoy, 1985). In 1838 Rokitansky reported 19 adult autopsy cases of uterovaginal agenesis, including 3 with associated unilateral renal agenesis. In 1910 Küster recognized urologic associations, such as renal ectopy and agenesis, along with skeletal deformities. Hauser and Schreiner (1961) brought further attention to the frequent association of renal and skeletal anomalies in these patients and stressed the differences between patients with these findings and those with testicular feminization.

The Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome, as the entity of **müllerian** aplasia has come to be known, results from failure of the sinovaginal bulbs to develop and form the vaginal plate (Fig. 47.17). This may be caused by improper induction of the sinovaginal bulbs from the neighboring uterovaginal primordium. Chronologically, the uterovaginal canal develops at a point in embryogenesis during which other critical mesodermally derived organ systems are also forming, which in part explains the many associated findings. Müllerian aplasia also has been associated with maternal deficiency of galactose-1-phosphate uridyltransferase (Cramer et al., 1996). In contrast to vaginal atresia, the hymenal fringe is usually present, along with a small vaginal pouch, because they are both derived embryologically from the urogenital sinus. Most patients with MRKH syndrome are initially evaluated by the physician after the expected age of menarche because of primary amenorrhea. This syndrome is in fact second only to gonadal dysgenesis as a cause of primary amenorrhea. A minority of patients have cyclic abdominal pain caused by retention of menstrual fluid in the uterus. Physical examination reveals absence of the vagina. Inguinal hernia is less common in this disorder than in complete androgen insensitivity syndrome (Schmid-Tannwald and Hauser, 1973). The karyotype is that of a normal 46,XX woman. Radiographic evaluation is indicated to more fully delineate remnant müllerian structures and search for associated anomalies involving the renal and skeletal systems.

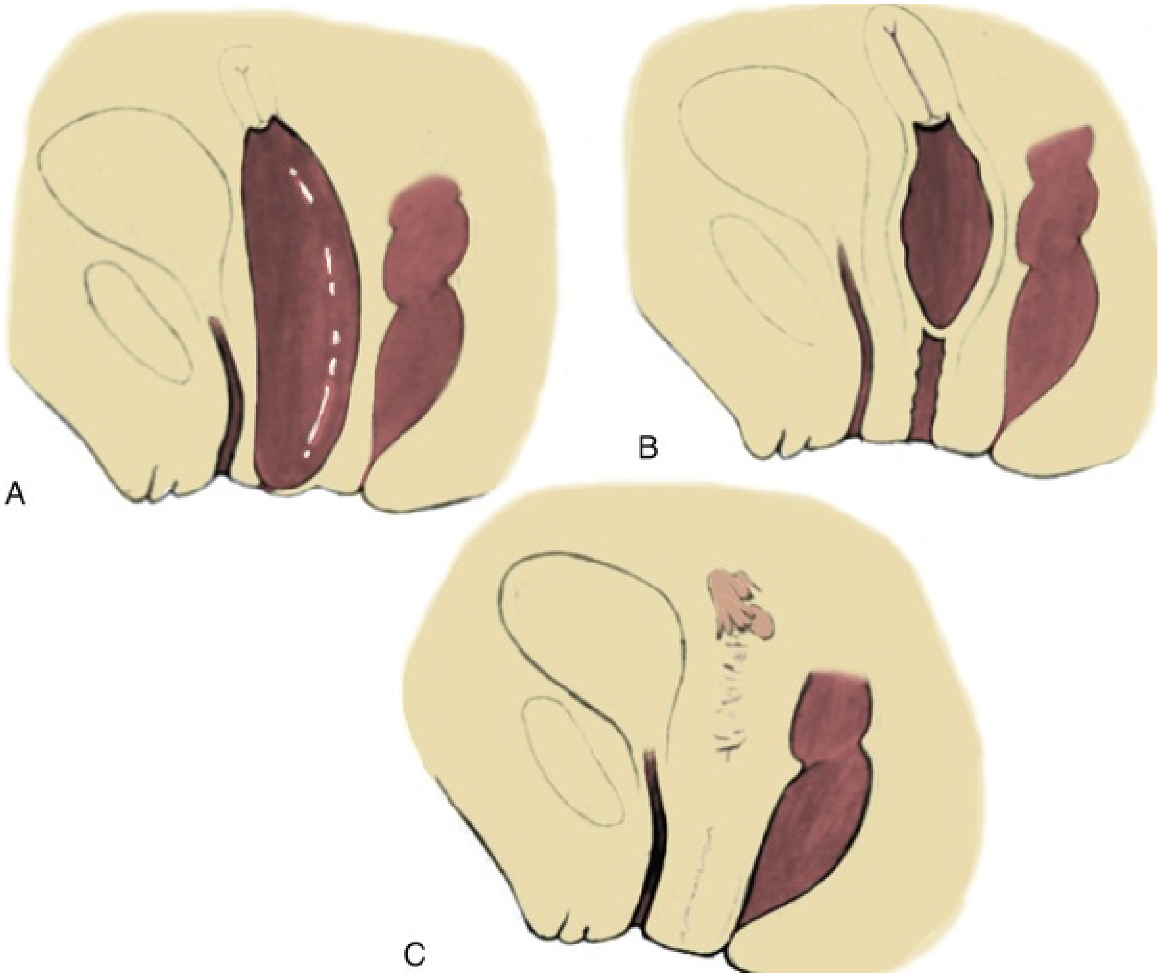

FIG. 47.17 Forms of vaginal obstruction. (A) Imperforate hymen. (B) Transverse vaginal septum. (C) Vaginal agenesis. (From Yerkes EB, Rink RC: What urologists should know about pediatric gynecologic abnormalities. *Contemp Urol* 14:12, 2002.)

Associated Findings

MRKH syndrome is associated with variable absence or hypoplasia of the cervix, uterus, and fallopian tubes. In approximately 10% of patients, a normal but obstructed uterus or rudimentary uterus with functional endometrium is present (Bates and Wiser, 1985; Murray and Gambrell, 1979; Singh and Devi, 1983). In one of the largest single series, Salvatore and Lodovicci (1978) reported that of 91 patients with vaginal agenesis, almost 25% lacked a uterus, 55% had a solid rudimentary uterus, and the remaining 30% had other abnormalities of this organ. In addition they demonstrated that, although the fallopian tubes were normal in 32% of cases, they were rudimentary in almost 50% and completely absent in 10%. Although occasionally cystic, the ovaries were always present and functional (Salvatori and Ludovicci, 1978). It was subsequently recognized, based on the morphology of the retained müllerian structures, that MRKH syndrome could be divided into the typical and atypical forms (Schmid-Tannwald and Hauser, 1977).

In the typical form of MRKH syndrome (type A) the patient has symmetrical uterine remnants and normal fallopian tubes. The atypical form (type B) is characterized by asymmetrical uterine buds and/or abnormally developed fallopian tubes. This distinction is important because the overwhelming majority of associated findings and other organ systems have been reported to be present with the atypical form, whereas in the typical form these findings are usually absent (Strubbe et al., 1992, 1993).

The prevalence of type A versus type B variants of MRKH syndrome appears to vary between different racial and ethnic groups. Although 46.2% of cases have recently been shown to be type B in a Caucasian cohort, the percentage of cases can vary between 7% and 28% among various Chinese populations (Deng et al., 2019).

The association between vaginal agenesis and developmental abnormalities of the kidney was first recognized by Rokitansky (1838). Approximately one-third of patients were found to have abnormal renal findings on intravenous pyelography or ultrasound examination (Strubbe et al., 1993). Renal anomalies are present almost exclusively in patients with the atypical subtype of vaginal agenesis (type B). In the series by Strubbe et al. (1993), 34 of 51 patients with type B anatomy had renal anomalies, but none of the 40 patients with type A anatomy demonstrated such a deformity. A meta-analysis published by Griffin et al. (1976) demonstrated that the renal anomaly consists of either unilateral renal agenesis or ectopia of one or both kidneys in 74% of those affected. The close proximity of the mesonephric and paramesonephric structures during the early phase of fetal development is thought to be the reason for this frequent association of renal anomalies. Not surprisingly, the converse is also true: the incidence of associated genital anomalies in female patients with renal anomalies ranges between 25% and 89% (Thompson and Lynn, 1966).

Associated congenital abnormalities of the skeletal system have been described in 10% to 20% of cases (Strubbe et al., 1987; Turunen, 1967; Willemsen, 1982). Congenital fusion (failure of segmentation) of the cervical vertebrae, known as the Klippel-Feil syndrome, occurs approximately once in 30,000 to 40,000 live births (Gunderson et al., 1967). The association between this abnormality of cervical somite development and vaginal agenesis was first recognized by Duncan (1977). He proposed the term *MURCS association* to describe a combination of **Mü**llerian duct aplasia, **R**enal aplasia, and **C**ervicothoracic **S**omite dysplasia, which many believe is caused by a generalized disordered development of mesodermal differentiation during the fourth week of fetal life (Duncan et al., 1979). Strubbe et al. (1992) demonstrated that the Klippel-Feil abnormality was found only in patients with the atypical form of MRKH syndrome (type B). Additional, albeit less common, skeletal abnormalities include scoliosis and abnormalities of the hands and face (Fisher et al., 2000; Willemsen, 1982). Abnormal pelvic vasculature has also been reported. Although this does not appear to occur as frequently as in other conditions that affect the female genitalia (i.e., cloaca), awareness of this possibility is important to avoid surgical misadventure (Bailey et al., 2010). Unlike müllerian anomalies that are associated with an increased incidence of abnormal cloacal septation, vaginal agenesis is not associated with an increased incidence of lumbosacral spinal disorders or occult spinal dysraphism (Gunderson et al., 1967).

Key Points: Disorders of Vagina

- Anomalies of the female reproductive system can be grouped into three main categories, those resulting from (1) hypoplasia or agenesis, (2) vertical fusion, and (3) lateral fusion.
- Transverse vaginal septa are believed to arise from a failure in fusion or

canalization (or both) of the urogenital sinus and müllerian ducts.

- Vaginal atresia occurs when the urogenital sinus fails to contribute to formation of the lower (distal) portion of the vagina.
- Vaginal agenesis is congenital absence of the proximal portion of the vagina in an otherwise phenotypically, chromosomally, and hormonally intact female.
- MRKH syndrome, as the entity of müllerian aplasia has come to be known, results from failure of the sinovaginal bulbs to develop from the vaginal plate.

Vaginal Replacement Surgery

Creation of a Skin Neovagina.

Nonoperative and operative treatment options exist for this anomaly. Regardless of the method used, it can be very helpful to have the patient speak with someone who has previously undergone treatment before a specific management strategy is initiated (Ingram, 1981). The nonoperative approach, initially popularized by Frank (1938), involves gentle pressure of graduated hard dilators against the perineal surface to create a progressive invagination of the vaginal dimple. Ingram (1981) modified this technique by using a bicycle seat mounted on a stool. The nonoperative approach has greatest success when a vaginal dimple or pouch is already present (Williams et al., 1984, 1985). Gargollo et al. (2009) recently reported their experience with 69 females (mean 17.5 years) with vaginal agenesis treated with progressive perineal dilation. Success, defined as the ability to achieve sexual intercourse, vaginal acceptance of the largest dilator without discomfort, or vaginal length of 7 cm, was achieved in 88% of patients. The authors concluded that progressive perineal dilation should be offered as first-line therapy in adolescents with congenitally absent vagina.

Modifications of the Frank technique of perineal pressure have been developed that incorporate the surgical placement of tension sutures to aid in directing pressure from a Plexiglas dilator against the vaginal dimple (Vecchietti, 1979). The mold, often referred to as an “olive,” has sutures attached to it that are guided in a cranial direction through the vesicorectal space into the peritoneal cavity and brought out through the abdominal wall (Vecchietti technique). Tension is progressively increased via the abdominal wall sutures until sufficient vaginal length has been achieved. To avoid a formal laparotomy, laparoscopic techniques have been described to assist in dissection of the tissue plane for the Vecchietti technique (Borruto, 1992; Brucker et al., 2008; Fedele et al., 1996, 1999; Gauwerky et al., 1992). In more recent series by Fedele et al. (2006), all patients were found to have healthy vaginal mucosa, with the average vaginal length being almost 8 cm at 3 months. This technique has had limited use by urologists.

If the Frank method has been unsuccessful or is not accepted as a reasonable option by the patient or parents, creation of a functional vagina can be achieved by one of several techniques (Abbé, 1898; Hendren and Atala, 1994; McIndoe and Banister, 1938). The first landmark advance in vaginal reconstruction is attributed to Abbe in 1898. He described dissecting a canal between the rectum and urethra and lining this area with split-thickness skin grafts. This procedure was later popularized by McIndoe, and the procedure that now bears his name has gained wide acceptance in the United States (McIndoe and Banister, 1938). Preoperative preparation consists of full mechanical and antibiotic bowel preparation. A split-thickness skin graft is taken from the buttocks (0.018 to 0.022 inch) and tubularized over a stent (Fig. 47.18). A transverse incision is made at the level of the perineal dimple, and the potential space between the urethra and the rectum is carefully dissected up to the level of the peritoneal reflection. The graft and mold are then inserted into the potential space, and the labia minora are sutured around the stent to prevent extrusion during the initial healing phase (McIndoe, 1950). Many types of vaginal stents have been used for this purpose, including packed gauze, wood covered with a condom, silicone foam, acrylic, various metals, and inflatable vaginal stents (Barutcu and Akguner, 1998; Chen, 1994; Concannon et al., 1993). The Foley catheter is replaced by a suprapubic catheter and postoperatively the patient is kept at strict bed rest for 1 full week. A high incidence of postoperative vaginal stenosis necessitates postoperative vaginal dilation (Ingram, 1981). Excellent patient satisfaction has been reported in most large series (Alessandrescu et al., 1996; Martinez-Mora et al., 1992; Strickland et al., 1993).

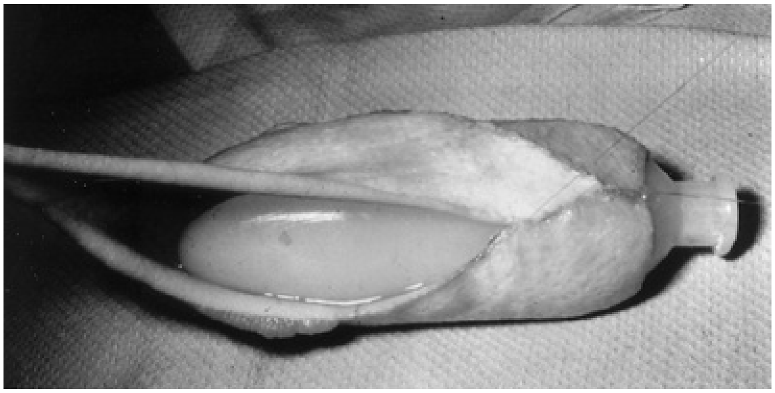

FIG. 47.18 McIndoe skin vagina sewn over vaginal stent.

Other options for creation of a neovagina with local tissues include the use of full-thickness skin graft from the buttocks or full-thickness skin flaps based on the labia majora. Those who champion the use of full-thickness skin grafts report a lower incidence of graft contracture than when split-thickness graft techniques are used (Sadove and Horton, 1988). The Williams (1964) vaginoplasty involves a creation of a vaginal pouch from the labia majora. The combination of this procedure and Frank-type dilation along the vaginal access can provide a satisfactory result. In 2014 Baker's team described the use of buccal mucosa for construction of the neovagina (Grimsby et al., 2014). Oral mucosa shares many properties similar to vaginal mucosa in that both are hairless, moist, and nonkeratinized stratified squamous epithelium. Oral mucosa possesses a dense layer of elastic fibers and a predilection for robust neovascularization resulting in excellent graft survival and function. Other authors have subsequently published favorable long-term anatomic and functional results using this versatile tissue (Li et al., 2014).

Many other surgical procedures have been developed for creation of a functional neovagina with various muscle flaps (e.g., pudendal thigh, rectus abdominis, buttock) (Dumanian and Donahoe, 1992; Joseph, 1997; Lilford et al., 1989; McCraw et al., 1976; Wang and Hadley, 1993). The pelvic peritoneum and human amnion are two other donor sites that have been used to create a neovagina (Ashworth et al., 1986; Davydov, 1977; Marquis et al., 2008; Morton and Dewhurst, 1986; Tamaya and Imai, 1991).

Between 2006 and 2013 Panici et al. performed McIndoe vaginoplasty procedures in 23 patients with MRKH syndrome using autologous cultured vaginal tissue. They reported that in all cases the vagina was of normal length and depth and that it allowed for normal and satisfying sexual intercourse (Panici et al., 2015). A subsequent quality-of-life study involving their first 39 patients revealed that 12 months after the procedure, 29 patients were engaged in regular sexual activity and had satisfactory sexual function compared with the general population (Sabatucci et al., 2018).

Creation of an Intestinal Neovagina.

Baldwin first described use of bowel for creation of the vagina in 1907. The procedure involved anastomosis of a U–shaped segment of sigmoid colon to the perineum with subsequent division of the intervening septum (Hensle and Dean, 1992). Additional experience with this technique was reported by Fall in 1940, but it did not gain widespread acceptance until the 1970s because of high patient morbidity and mortality (Fall, 1940; Pratt, 1972). Subsequent improvements in technique and postoperative care resulted in renewed enthusiasm for these techniques (Hendren and Atala, 1994; Hensle and Reiley, 1998; Tillem et al., 1998; Turner-Warwick and Kirby, 1990). Sigmoid, cecum, and small intestine have been used successfully for the creation of a functional neovagina.

The day before surgery, the patient undergoes full mechanical and antibiotic cleansing of the alimentary tract. The procedure is performed with the patient supine, the legs spread, and the knees bent (frog-leg position). In an older child, Allen stirrups can be used. For a sigmoid vaginoplasty, the intra-abdominal portion of the procedure begins by first identifying an appropriate length of distal sigmoid with a blood supply that will comfortably reach the perineum (Fig. 47.19). The distal end of the proposed segment was then divided and anastomosed to the perineum (Fig. 47.20). An intervening segment of sigmoid (approximately 3 cm) is excised to create a space between the oversewn proximal edge of the bowel vagina and the end of the sigmoid, which is anastomosed to the rectum. This maneuver prevents any overlap of suture lines and thereby has the potential advantage of limiting the incidence of fistula formation. The bowel vagina is thereafter fixed to the posterior peritoneum to prevent prolapse. Gosalbez (personal communication, 2009) described a modified Monti technique of bowel detubularization for vaginal replacement that can aid in allowing the segment to reach the perineum. By opening the colonic segment close to its mesentery along one side of the bowel and then re-tubularizing in a Heineke-Mikulicz fashion, as described by Monti, the reconfigured segment allows for the mesentery to be located at the most cranial end of the tube and allows the caudal end to extend more distally.

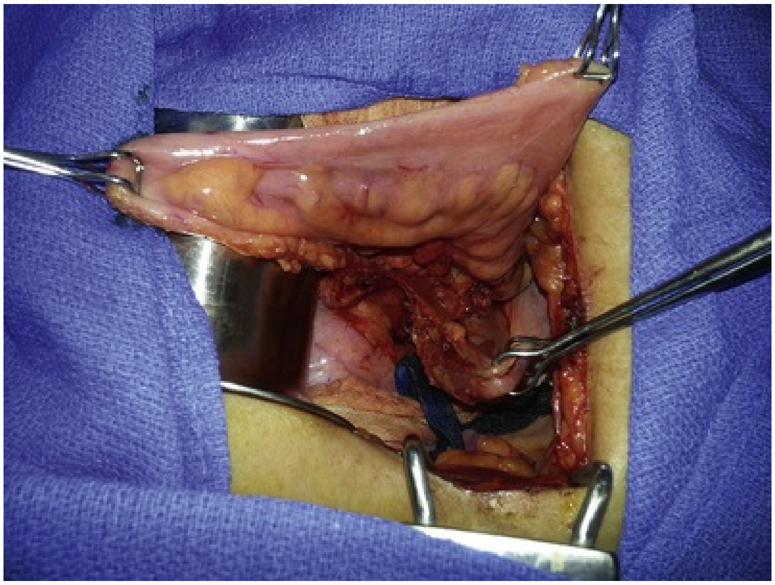

FIG. 47.19 Sigmoid segment harvested for bowel vagina. Clamp on peritoneum.

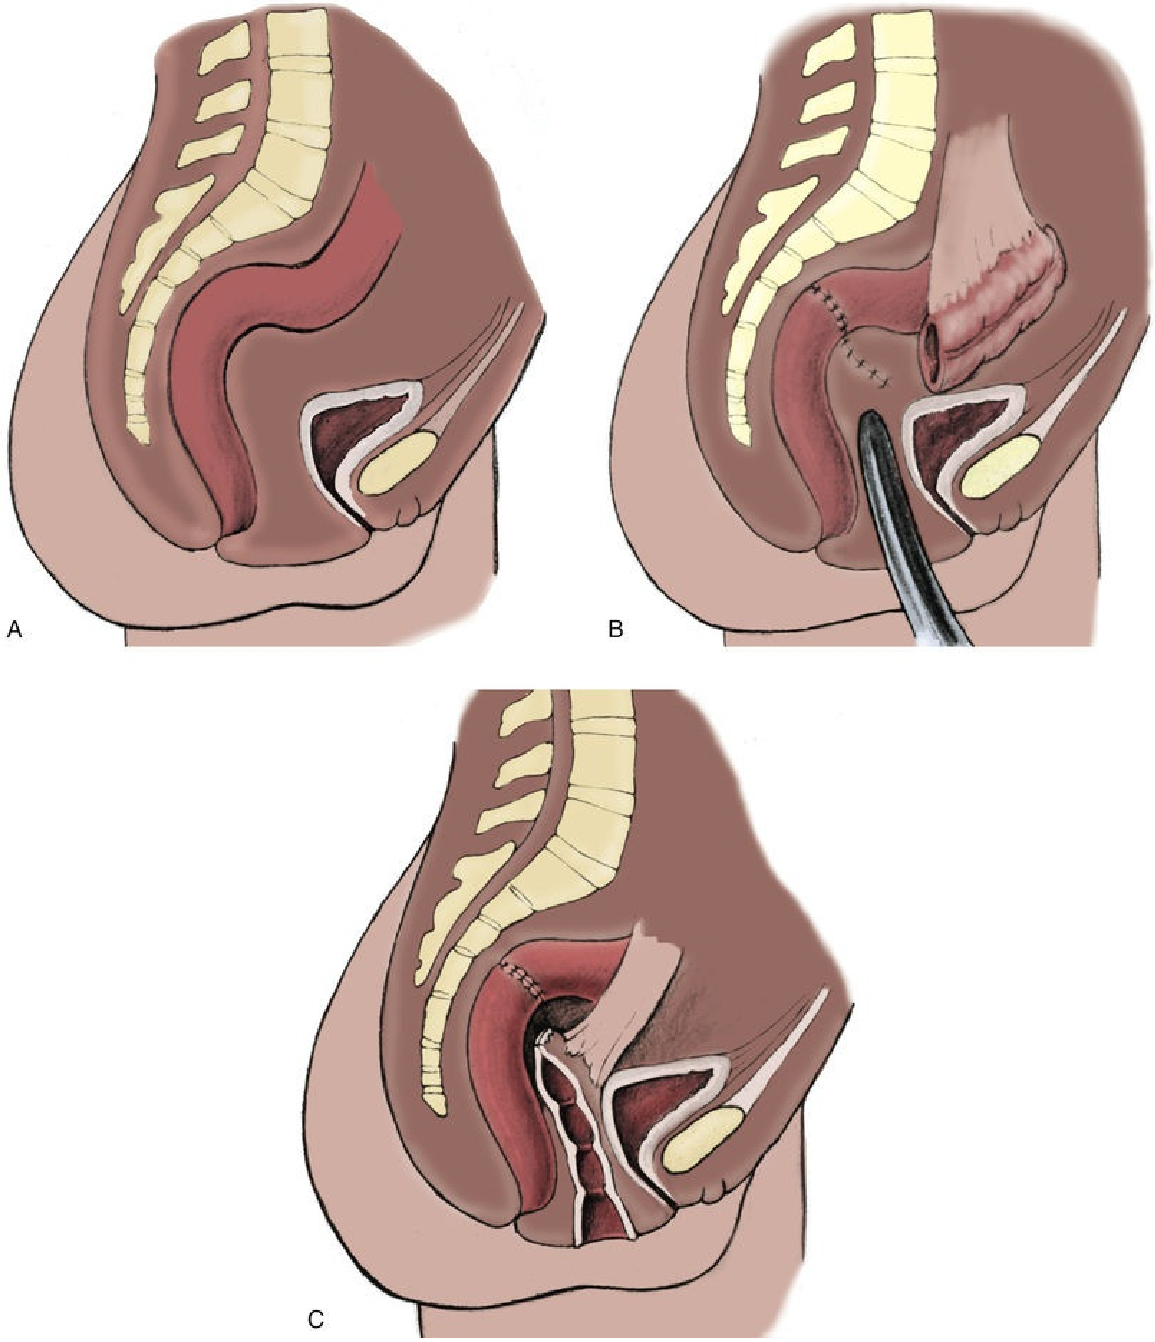

FIG. 47.20 (A) Vaginal agenesis. (B) Harvest of colonic segment and creation of vaginal space. (C) Colonic segment sewn in place.

Although we have had the most success with the sigmoid, a small bowel segment may be chosen with a vascular pedicle that is of adequate length to reach the perineum. After isolating an appropriate length of ileum and reestablishing bowel continuity, the segment is detubularized and reconfigured in a conical arrangement to provide increased internal diameter (Hendren and Atala, 1994). The segment is then brought down to the perineum and sewn in place, as for a sigmoid neovagina. To avoid a formal laparotomy, laparoscopically assisted techniques have been described for harvest and delivery of the bowel segment to the perineal location (Ota et al., 2000).

If there is a perineal dimple (i.e., the segment of vagina contributed by the urogenital sinus is present), the bowel segment should be anastomosed directly to it. When a direct perineal anastomosis is required, it is vital to create a large enough space between the rectum and bladder to avoid compromise of the intestinal blood supply. Creation of such a space can be facilitated by the use of progressively larger Hegar dilators. Gentle passage of the intestinal segment into position is facilitated by placing the segment in a large lubricated Penrose drain before transfer to the perineum.

The functional results of bowel vaginoplasty have been excellent. Of the 65 patients supported by Hendren and Atala (1994), 16 experienced mild inversion of the bowel segment, which in every case was amenable to simple trimming. Eight patients experienced mild stenosis that was later corrected by appropriate Z-plasties to increase the circumference of the mucocutaneous junction. Patient satisfaction is high, and the majority of patients who are old enough to engage in sexual relations are able to achieve adequate coitus (Hensle and Reiley, 1998).

Stenosis has been reported more frequently after the use of ileum (Hensle and Dean, 1992). This higher stenosis rate may be due not only to the more narrow ileal lumen but also to the limited mobility of the small bowel mesentery. As a result, the we and others believe that large intestine is the bowel segment of choice. Two specific indications for the use of an ileal segment for bowel vaginoplasty are previous irradiation of the deep pelvis and the absence of large intestine (i.e., cloacal exstrophy). When ileum is used, various methods of reconfiguration can be used to increase the diameter (Hendren and Atala, 1994). Advantages of a bowel vagina over the McIndoe procedure include the lubricating properties and mucus (which may help facilitate intercourse) and the decrease incidence of postoperative contracture (and hence reduced need for postoperative dilation). Disadvantages include the frequent need to wear pads because of the chronic vaginal discharge. Daily douching may be necessary to evacuate the mucus. Finally, the potential transmission of blood-borne pathogens such as hepatitis and human immunodeficiency virus may be increased (in comparison to a squamous epithelium–lined vagina) because of the poor barrier properties of the gastrointestinal tract.

All patients undergoing creation of a functional vagina with perineal skin require annual examination because of reports of condylomata acuminata and squamous cell carcinoma involving grafts (Buscema et al., 1987; Duckler, 1972; Rotmensch et al., 1983). Annual examination of the bowel vagina is also indicated because adenocarcinoma has been identified after this procedure (Andryjowicz et al., 1985).

The optimal timing of surgery remains a source of debate. The majority of surgeons who favor the McIndoe procedure for construction of a neovagina think it is better to wait until adulthood to perform the procedure because a degree of maturity is required to consistently perform daily dilations. Many surgeons who favor the use of bowel for neovaginal reconstruction do not think vaginoplasty should be deferred until the patient reaches adulthood. Hendren and Atala (1994) think that delaying creation of a neovagina until adulthood may be psychologically traumatic to a young girl. We have based our timing on the underlying diagnosis and need for a neovagina.

Special Considerations: Cervical Atresia

Cervical agenesis is an uncommon disorder associated with symptoms common to other obstructive entities of the female reproductive tract (i.e., primary amenorrhea, cyclic or chronic abdominal pain). Failure to establish the correct diagnosis and thereby choose the appropriate method of surgical intervention can be fraught with disaster and possible patient mortality. MRI is the most useful radiographic modality for establishing this diagnosis (Fig. 47.21). In many circumstances the patient is best served by hysterectomy with subsequent vaginal replacement by one of the previously described techniques (Cukier et al., 1986; Rock et al., 1982). Successful direct anastomosis of the neovagina to the uterine remnant has been reported. Deffarges et al. (2001), in describing their experience with uterovaginal anastomosis, reported a 40% pregnancy rate in patients attempting to conceive. Cerclage was performed in only one case. All deliveries were by cesarean section. Although this procedure appears to be successful in the majority of cases, absence of the normal endocervical barrier can leave the patient predisposed to development of life-threatening ascending infection (Casey and Laufer, 1997; Maciulla et al., 1978; Niver et al., 1980).

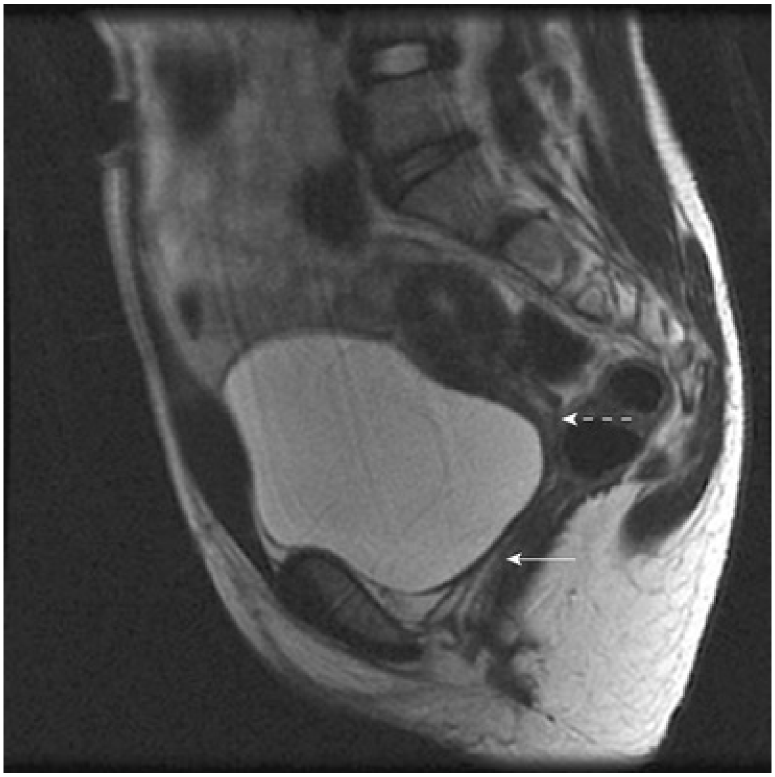

FIG. 47.21 Magnetic resonance imaging scan of the pelvis in a 12-year-old girl with Klippel-Feil syndrome and associated proximal vaginal and cervical atresia. The *solid arrow* points to the most cranial portion of the perineal vaginal pit. The *dashed arrow* point to the most inferior aspect of the uterus, where no cervical impression can be appreciated.

In cases in which it has not been possible to successfully achieve continuity between the uterus and vagina, in vitro fertilization plus transmyometrial embryo transfer has been performed, with subsequent delivery of a healthy fetus by cesarean section (Anttila et al., 1999; Lai et al., 2001). If this option is considered, hormonal blockade of the endometrium until the time at which the patient desires to initiate a pregnancy is indicated to minimize discomfort and reduce the incidence of endometriosis from retrograde menstrual flow in the fallopian tubes.

Key Points: Vaginal Replacement Surgery

- The McIndoe procedure (skin neovagina) is associated with a higher incidence of postoperative vaginal stenosis than a bowel neovagina.
- Vaginal stenosis after creation of an intestinal neovagina is more common

with ileum than large bowel.
- Vaginal reconstruction extending from the perineum to the uterus should be avoided in patients with cervical agenesis (because of the potential life-threatening complication of ascending bacterial infection).

Abnormalities of Lateral Fusion

Most abnormalities of lateral fusion have no functional significance. With the exception of those with uterus didelphys and unilateral vaginal obstruction, most patients are asymptomatic. Although an exhaustive description of the anomalies of lateral fusion is beyond the scope of this chapter, some general comments can be made (Fig. 47.22).

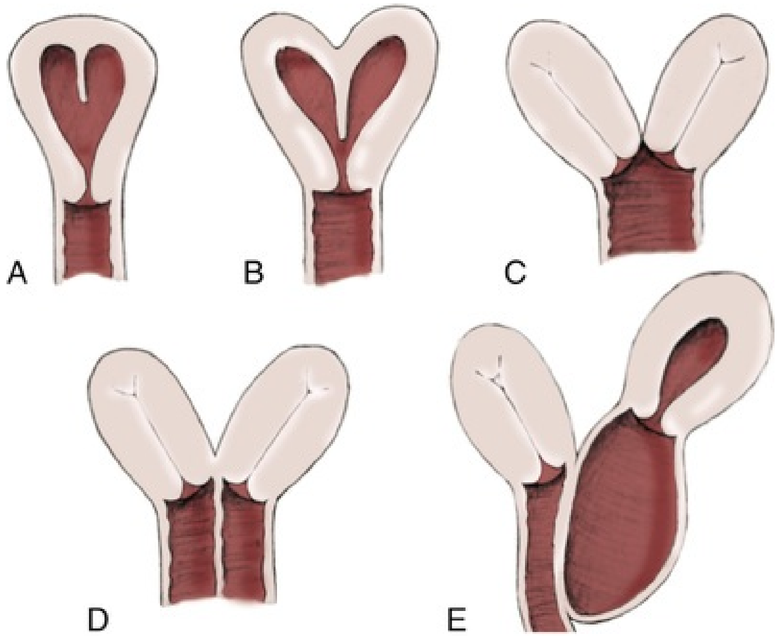

FIG. 47.22 Fusion anomalies of the müllerian system. (A) Bicornuate uterus (partial). (B) Bicornuate uterus. (C) Uterine duplication. (D) Complete uterine and vaginal duplication. (E) Duplication of the uterus and cervix with a unilateral imperforate vagina. (From Yerkes EB, Rink RC: What urologists should know about pediatric gynecologic abnormalities. *Contemp Urol* 14:12, 2002.)

True duplication of the uterus is a rare event (Fig. 47.23). This anomaly results from duplication of the müllerian ducts and subsequent doubling of the reproductive structures on one or both sides. The much more frequently encountered anomaly of uterine didelphys consists of two separate uterine cavities and cervices as a result of failed resorption of the common medial wall of the paired müllerian duct structures during development. Although up to 75% of patients also have a septate vagina, most have adequate reproductive outcomes and do not require surgical intervention. If later in life the patient experiences difficulty with intercourse, vaginal delivery, or the need to use two tampons, surgical excision of the vaginal septum should be undertaken. If only the most cranial portion of the septum remains, a bicornate uterus will result. The vagina is typically normal, and surgical incision of the uterine septum is rarely indicated except in cases of recurrent pregnancy loss (DeCherney et al., 1986).

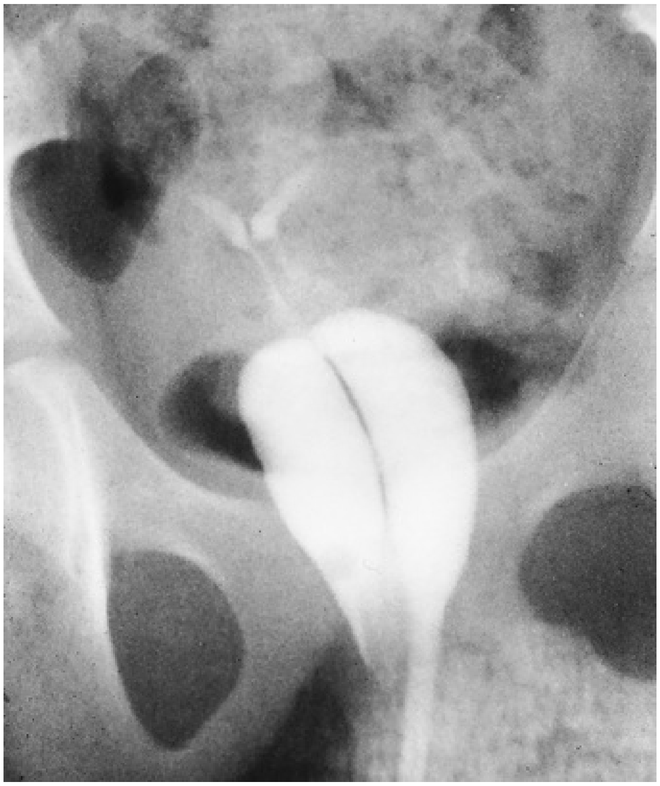

FIG. 47.23 Genitogram of complete müllerian duplication (septated vagina and separate uteri).

Duplication of the Uterus and Cervix With Unilaterally Imperforate Vagina (Herlyn-Werner-Wunderlich Syndrome).

Although the majority of obstructive lesions are caused by abnormalities of vertical fusion, occasionally an obstructive process can be encountered in the context of an abnormality of lateral fusion (Fig. 47.24). Otherwise known as the

Herlyn-Werner-Wunderlich syndrome (HWWS), more than 50 cases of uterus didelphys with unilateral imperforate vagina have been reported in the Western literature (Allan and Cowan, 1963; Burbige and Hensle, 1984; Herlyn and Werner, 1971; Wunderlich, 1976). As with other obstructive disorders, the patient may have cyclic or chronic abdominal pain. However, unlike other obstructive processes, duplication anomalies with unilateral obstruction do not result in primary amenorrhea. On physical examination, a unilateral abdominopelvic mass that terminates in a bluish bulge in the lateral vaginal wall is often appreciated (Eisenberg et al., 1982). Abdominal ultrasonography and MRI are excellent at defining the anatomy in a suspected case of unilateral noncommunicating uterine horn. Renal anomalies are frequently encountered on the side ipsilateral to the obstructed system, with renal agenesis being the most common (Eisenberg et al., 1982; Tridenti and Bruni, 1995). A prompt and accurate diagnosis is necessary to prevent injury to the genital organs as a result of chronic cryptomenorrhea and endometriosis.

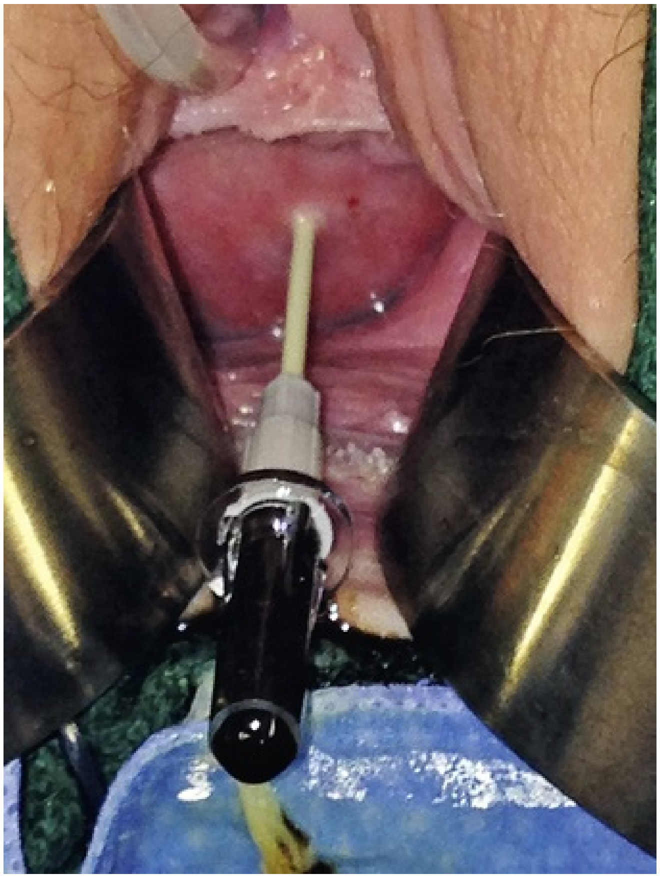

FIG. 47.24 Duplication of uterus vagina with unilateral imperforate vagina. View through vagina with angiocatheter inserted into obstructed side.

Recently, Zhu et al. (2015), in their retrospective review of 79 patients seen over a 27-year period, noted a significant number of patients with incomplete obstruction of the hemivagina and therefore proposed that patients be categorized as either Class 1 (complete obstruction) or Class 2 (incomplete obstruction with the hemivagina draining through a small perforation). The ratio of Class 1 to Class 2 was 24 : 55 with the Class 2 patients seen at a significantly later age with a lower probability of endometriosis.

Treatment of HWWS consists of wide incision of the vertical vaginal septum to release the entrapped menstrual blood.

Acquired Disorders of the Female External Genitalia

Rhabdomyosarcoma

Vaginal rhabdomyosarcoma most often manifests as a grapelike cluster of tissue emanating from the posterior aspect of the vestibule (Fig. 47.25). The mean age of patients with primary vaginal tumors is younger than 2 years (Hays et al., 1988). Of all the female genital tract primary tumors, vaginal primary tumors appear to have the best prognosis. This excellent prognosis is thought to be the result of predominance of the embryonal cell type and the relatively early detection because of symptoms of bleeding (Hays et al., 1988). Once a tissue diagnosis has been made by biopsy, proper staging with abdominal and chest computed tomography and bone marrow biopsy is critical to the optimal stratification these patients into treatment protocols (Hays et al., 1985). Advances in chemotherapy have led to a reduction in the role of surgery for this disease with each subsequent Intergroup Rhabdomyosarcoma Study (IRS) trial: IRS-I, 100%; IRS-II, 70%; IRS-III, 30%; IRS-IV, 13% (Andrassy et al., 1999). After chemotherapy, local resection may be required, but unlike other malignancies of the vagina, wide excision of the involved organ has no role except for persistent or recurrent disease (Hensley, 2000).

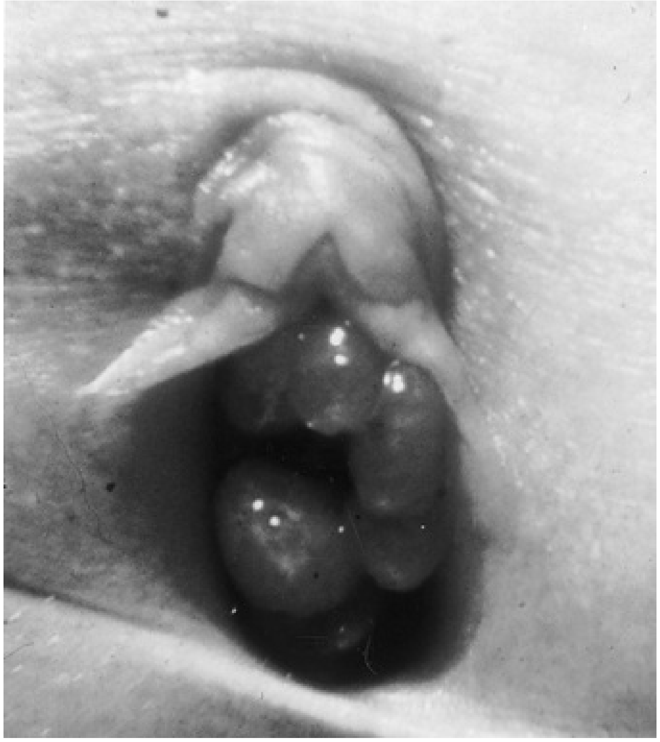

FIG. 47.25 Vaginal rhabdomyosarcoma.

Labial Adhesions

Labial adhesions, also referred to as labial agglutination and synechia vulvae, are the most common interlabial abnormality identified in children, ranging in incidence from 0.6% to 1.8% (Leung et al., 1993; Norbeck et al., 1993; Fig. 47.26). This condition occurs predominantly in the first 2 years of life, with a peak instance between 13 and 23 months. Fusion of the labia minora originates at the posterior fourchette and progresses for a variable distance toward the clitoris. It is important to differentiate this condition from the more serious entity of fusion of the labia majora, as is seen in certain disorders of sexual development. It has been hypothesized that hypoestrogenism may play a role in adhesion of the labia minora. Labial adhesions have not been reported in newborn children, presumably because of the protective effect of maternal estrogen (Leung et al., 1993). However, the etiologic role of the hypoestrogenic state has been brought into question by a number of authors (Caglar, 2007; Pulvino et al., 2008). Caglar (2007) measured circulating estradiol levels in 59 girls with labial adhesions and 60 control patients. He demonstrated no difference in the circulating level of estrogen in these 2 patient groups. It has been shown that estradiol may enhance wound re-epithelialization by promoting heparin-binding epidermal growth factor production in keratinocytes (Kanda and Watanabe, 2005). If there is a beneficial effect of topical estrogen, it may be to promote healing after the adhesions have been separated. Nonhormonal factors may play an etiologic role in the formation of labial adhesions (Papagianni and Stanhope, 2003). Local irritation and tissue trauma appear to be important inciting events in many cases. Adhesions can rarely be associated with sexual abuse; in such cases, additional physical findings are often noted, including hematoma and lacerations (McCann et al., 1988). Although labial adhesions are usually asymptomatic, urine pooling within the vagina may lead to postvoid dribbling, and perineal irritation may make it difficult to obtain an accurate urinalysis sample or perform radiographic procedures.

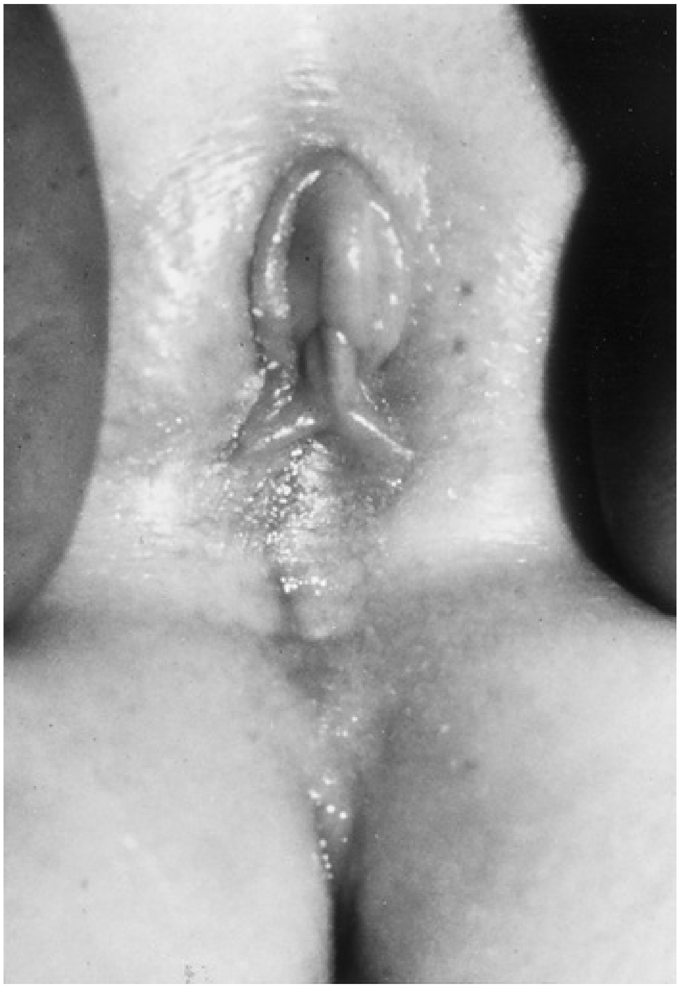

FIG. 47.26 Labial adhesions.

Most children with labial adhesions do not require treatment unless they are symptomatic. With the rate of spontaneous resolution reported to be as high as 80% within 1 year, asymptomatic labial adhesions can comfortably be observed (Pokorny, 1992). When necessary, treatment ranges from the topical application of various agents to surgical division. A recent randomized controlled trial of estradiol versus petroleum-based emollient demonstrated an increased success rate in the estradiol treatment arm (Dowlut-McElroy et al., 2019). The topical application of conjugated estrogens has been reported to be successful in separating adhesions in up to 90% of patients (Khanam et al., 1977; Leung et al., 2005). Concern over the possible side effects of breast budding and hyperpigmentation from prolonged use of conjugated estrogen led Myers et al. (2006) to treat a cohort of 19 prepubertal patients with topical betamethasone (0.05%). The authors reported success in 13 (68%) patients after administering 1 to 3 courses of twice-daily therapy for 4 to 6 weeks. It is important to have the family place the cream directly on the labia minora. In addition, it is helpful to have the family perform the labial pull-down procedure (i.e., grasping the labia majora and gently pulling in a caudal and lateral direction) a few times a day to put light stress on the midline adhesions and therefore facilitate their separation. If topical therapy is not successful, manual separation in the outpatient setting may be indicated. After the application of EMLA cream to the introitus, gentle pressure is applied to the thin connecting membrane with the aid of a lubricated probe. Rarely, in cases in which adhesions are extremely dense, surgical revision is required. Some authors advocate oversewing the separated edges with 7-0 chromic suture (Nurzia et al., 2003). We have not found this to be necessary if the family is properly educated to keep the labia separated after the procedure. Recurrence rates appear to be similar when comparing children who have undergone manual separation (16.7%) versus surgical separation (15.4%), emphasizing the importance of having family continue to separate the labia after separation has been achieved (Muram, 1999). In cases of highly recalcitrant dense adhesions, external use of an oxidized cellulose barrier has been proposed in adults but has not been used in the pediatric setting (Wyman et al., 2018).

Female Circumcision (Infibulation)

Acquired vaginal obstruction may be secondary to a number of ritual female genital mutilation (FGM) procedures that are widespread in many countries in Africa (stretching in a band from the Horn of Africa through central Africa to parts of Nigeria), the Middle East, and Muslim populations of Indonesia and Malaysia (Dorkenoo, 1996; Toubia, 1994). Although similar procedures were prescribed for use in British women during the 19th century for the treatment of ailments ranging from epilepsy to lesbianism, all forms of genital mutilation are now illegal in these Western countries. Population-based prevalence data from 30 countries estimate that approximately 200 million girls and women have been subjected to female genital cutting. An estimated 3 million African girls will be subjected annually to this practice (Unicef, 2016).

A survey of reproductive age women in Ethiopia has revealed that the prevalence of FGM is associated with ethnicity and socioeconomic status. In their study of nearly 29,000 women, Setegn et al. (2016) noted that FGM was more common among those of Muslim ethnicity and families of higher socioeconomic status. In contrast, the likelihood of experiencing FGM was inversely correlated with the level of maternal education.

The age at which this procedure is performed ranges from birth to just before marriage. However, it is typically performed on preadolescent children between the ages of 4 and 10 years, most commonly at age 7 (American Medical Association, 1995). The procedure is usually performed without anesthesia in the context of a ceremony designating the rite of passage into adult society (American Medical Association, 1995). The extent of the mutilation varies according to ritual, but the practice predates Islam and is therefore not a part of a religion (McCaffrey et al., 1995). In many countries the women have a deinfibulation procedure performed just before consummating the marriage.

The type of mutilation ranges from simple excision of the prepuce of the clitoris (termed *sunna*) to complete excision of all elements of the vulvar region (McCaffrey et al., 1995). Toubia (1994) classified the more extensive female genital mutilation procedures according to the amount of tissue destruction:

- Type I: Complete or partial removal of the clitoris
- Type II: Excision of the clitoris and a portion of the labia minora
- Type III: Excision of the entire clitoris and labia minora with incision of the labia majora along its medial aspect to create a raw surface. The anterior two-thirds of the of the labia majora are approximated to cover the urethra and introitus, with the lower third at the level of the posterior fourchette left for the passage of urine and menstrual fluid.

- Type IV: Excision of the entire clitoris and labia minora with near complete approximation of the labia majora, leaving only a pinhole opening at the posterior fourchette for the passage of urine and menstrual fluid (Fig. 47.27).

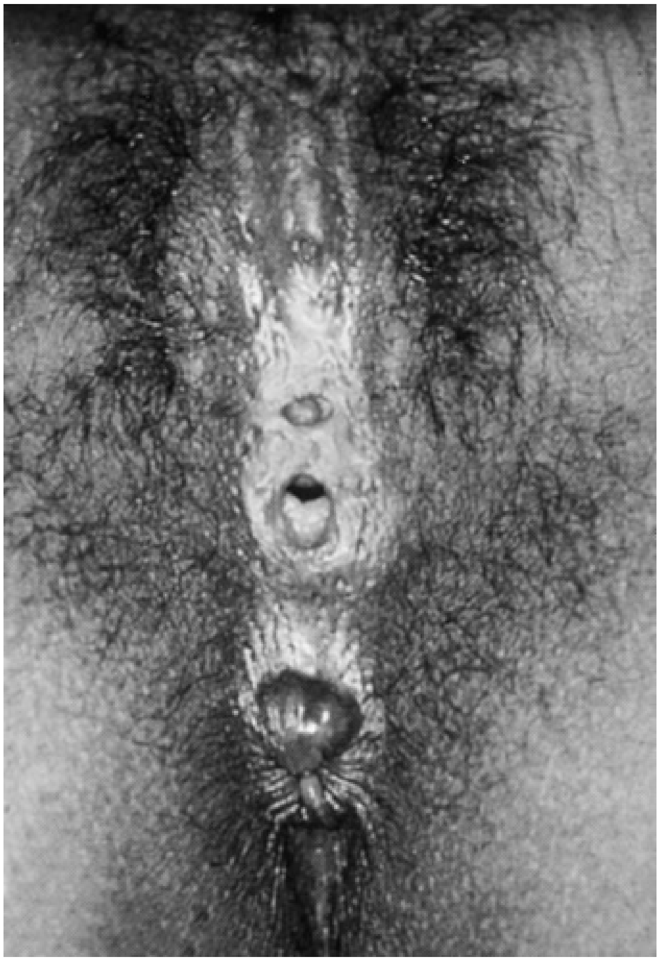

FIG. 47.27 Female infibulation. Note the scarred labia majora with only a pinhole opening for the passage of menstrual fluid and urine. (From Gonzales ET, Bauer SB, editors: *Pediatric urology practice,* Philadelphia, 1999, Lippincott Williams and Wilkins, p 599.)

- Closing of the introitus, typically referred to as infibulation or pharaonic circumcision, is performed by a variety of means, including absorbable and nonabsorbable suture materials, thorns, and twigs. The child's legs are then bound for up to 40 days to ensure secondary healing in the ventral midline (McCaffrey et al.,

1995).

The physical, psychological, and reproductive repercussions of these forms of genital mutilation are numerous and include immediate destruction and infection of local tissues (e.g., rectum, urethra). Long-term risks include chronic pain, recurrent urinary tract infection and vaginal infections, dysmenorrhea, dyspareunia, and apareunia. For individuals with the most narrowing, additional “surgeries” to revise the introital opening may be necessary for intercourse and vaginal delivery (Aziz, 1980; Toubia, 1994).

Care of the patient who has undergone infibulation must be individualized not only to provide functionality but also to respect the cultural and ritual desires of the woman. Educating the patient about the normal appearance of the external female genitalia is critical. Visual aids, including photographs or hand-drawn illustrations of the patient's anatomy and the planned revision, have been used as part of informed consent to avoid misunderstanding.

Complications resulting from infibulation are dependent on the degree of tissue destruction that results from the mutilation. A close assessment of all genital structures is required to make an accurate assessment. Complications resulting from closure of the introitus can range from urinary tract infections to retention of menstrual flow with endometriosis and even formation of calculus secondary to stagnation of urine in the vagina (Yusuf et al., 2008).

The broad spectrum of acquired anatomic anomalies secondary to FGM requires that reconstructive efforts be individualized.

Simple opening of the midline scar tissue with subcuticular closure of each edge has a high success rate. Nour et al. (2006) reported their results in 40 patients in which 92% could be reached for adequate follow-up. All of the patients who responded and their husbands were satisfied with the results, felt their appearance had improved, and were sexually satisfied.

As may be expected, more complex reconstructive efforts involving the clitoris may be less satisfying depending on the degree of injury to the glans and corpora. Foldès et al. have reported their extensive experience of nearly 3000 women with a mean age of 29 years who underwent genital reconstruction. They reported that reconstructive surgery after female genital mutilation was associated with reduced pain and restored pleasure. Of the 841 women who returned for follow-up, 51% reported that they were able to experience orgasm. The conclusions of this study are limited by the low 1-year follow-up (29%) among the cohort studied (Foldés et al., 2012).

Condyloma Acuminata

The incidence of genital warts in children has increased over the past 5 decades (Leclair et al., 2012). Although the majority are found in the perianal region, involvement of the vestibule can at times occur. The treatment of condyloma acuminatum in pediatric patients is difficult, with a wide range of treatment options that yield variable success. The decision as to which treatment is most ideal depends on patient age and location and the severity of the lesions. Although very high suspicion for sexual abuse is warranted, perinatal transmission is also a possible mechanism. De Jesus et al. (2001) reported perinatal transmission occurred in 7 of their 17 patients.

Reports of spontaneous resolution exist (Leclair et al., 2012). Allen and Siegfried (1998) reported that spontaneous resolution of pediatric condyloma occurred in more than half of their subjects. Medical therapy can be effective. Imiquimod, an immune response modifier that works through the Toll-like receptor 7 pathway, has been used extensively in adults. Leclair et al. (2012) found this to be highly effective in a young child with rapidly progressing lesions that were not amenable to surgical resection. Although carbon dioxide laser ablation of anogenital lesions is straightforward, lesions directly involving the vestibule may be more challenging. In one series of 17 patients in whom 12 were female, nearly 70% responded favorably to CO_2 ablation therapy (Johnson et al., 1997). Because the cause of condyloma acuminatum is human papilloma virus (HPV), authors emphasize the primary prevention of HPV infection through vaccination as a key component in decreasing the incidence of this disease (Thornsberry and English, 2012).

Inguinal Hernias

Hernias occur far less frequently in girls than boys, with a ratio between 1 : 5 and 1 : 10 reported in major series. Although usually an isolated event, this anatomic finding can be the manifesting symptom in a child with CAIS. Multiple authors have reported a 1% incidence of CAIS in patients with an inguinal hernia (Hurme et al., 2009; Sarpel et al., 2005). It is therefore imperative that all phenotypic females with inguinal hernia be evaluated to determine if they are a genetic male. Various methods of determining whether the patient has CAIS are available to the clinician. A karyotype, although definitive, is costly and therefore not obtained routinely by most practitioners. A pelvic sonogram to evaluate for the presence of (or absence) of a vaginal stripe can also be obtained but has the similar drawback of added cost.

Simple evaluation by way of vaginoscopy at the time of hernia repair will reveal if the cervix is present. A patient with CAIS also may have a significantly shorter vagina. While the hernia is being repaired, inguinal laparoscopy can be performed to study the contralateral gonad and evaluate for the presence of the uterus. The round ligament will be uniformly absent in genetic males.

Key Points: Acquired Disorders of the Female Genitalia

- Most children with labial adhesions do not require treatment unless they are symptomatic.
- FMG affects an estimated 200 million women worldwide.
- *Condylomata acuminata* can be acquired through perinatal transmission from the mother.
- Inguinal hernias in a female should alert the clinician to the possible diagnosis of CAIS.

Disorders of Sexual Development

Etiology, Evaluation, and Medical Management

Richard Nithiphaisal Yu MD, PhD, David Andrew Diamond MD

Disorders of sexual development are among the most fascinating and complex disease processes encountered by the urologist. This field has undergone a striking evolution over the past few decades. Remarkable advances in molecular biology and genetic research have provided new insight into the precise mechanisms responsible for sexual differentiation and for specific DSDs. In addition, there has been a major shift in nomenclature to promote precise communication among colleagues and respect for the sensitivity of patients by eliminating terms such as *pseudohermaphroditism,* which have been regarded as pejorative by patients. The term *intersex disorders* has been replaced by *disorders of sexual development*.

Normal Sexual Development

Under normal circumstances, sexual development is a dynamic and sequential process. According to the Jost paradigm, three steps must occur: establishment of chromosomal sex at fertilization, which determines development of the undifferentiated gonads into testes or ovaries, and subsequent differentiation of the internal ducts and external genitalia as a result of endocrine functions associated with the type of gonad present (Jost et al., 1973). Therefore, sexual development occurs as a result of different but complementary processes: genotypic effects, phenotypic events, and gender identity formation. Interference with this highly ordered process at any step can result in a disorder of sexual development.

Normal Genotypic Development

Chromosomal Sex

In 1921, Painter demonstrated cytologically that humans have X and Y chromosomes. Based on chromosomal studies of *Drosophila,* it was assumed that sex was determined by the X chromosomes possessed by the individual (Bridges, 1921). The Y chromosome was thought to impart no genetic information until karyotyping of mammalian chromosomes, developed in the 1950s, demonstrated that the Y chromosome specified development of the testis. Specifically, reports in the late 1950s describing the karyotype 47,XXY as male with Klinefelter syndrome and 45,XO as female with Turner syndrome demonstrated that the presence of a Y chromosome, independent of the number of X chromosomes, resulted in the development of a male embryo, whereas in the absence of a Y chromosome the embryo developed as a female (Ford et al., 1959; Jacobs and Strong, 1959). Therefore, the Y chromosome appeared to possess a gene or genes that determined the destiny of the bipotential gonad as a testis or ovary. **In the human, the hypothetical Y-chromosomal gene was termed the *testis-determining factor (TDF)*.**

During the following years, the search for the TDF was the focus of intense research. The observation that antibodies raised in inbred female mice transplanted with male skin grafts resulted in graft rejection, whereas female-to-male skin grafts were accepted in the same strain of mice led to the proposal that the histocompatibility-Y, or H-Y, antigen was the product of TDF (Eichwald, 1955). Assays for quantifying H-Y antigen were developed. With the use of these assays, it was discovered that the presence of a testis resulted in serologically detectable levels of H-Y antigen. This was confirmed in normal patients, patients with DSDs, and males of other species. **Therefore, it was believed that the *H-Y* gene was the TDF** (Wachtel, 1977). **This theory was considered valid for more than 10 years.**

The application of molecular techniques to evaluate Y-chromosomal sequences present in XX males and deletions of the Y chromosome in XY females led to the cloning of TDF (Lukusa et al., 1992). **Deletion maps based on the genomes of these individuals were constructed by a number of laboratories, and TDF was mapped to the most distal aspect of the Y-unique region of the short arm of the Y chromosome, adjacent to the pseudoautosomal boundary** (Fig. 48.1).

FIG. 48.1 Genetic map of the short arm of the human Y chromosome. The pseudoautosomal region, where genetic crossing over may occur between sex chromosomes, is highlighted in yellow. The *SRY* and *ZFY* loci are located near the pseudoautosomal boundary on the short arm of the Y chromosome at the terminal end *(pter)*. The SRY gene encodes the molecular switch that promotes gonadal sex determination. (From Lahn BT, Page DC. Functional coherence of the human Y chromosome. *Science*. 1997;278:675–680.)

SRY

The locus for TDF was ultimately narrowed down to a 35-kb region adjacent to the pseudoautosomal boundary (Fig. 48.2). Using probes from this region, Sinclair et al. (1990) discovered a single-copy male-specific sequence that was evolutionarily conserved. This gene was termed *SRY* (sex-determining region Y gene) in humans and *Sry* in mice. Analysis of the SRY protein sequence demonstrated a highly conserved, 78–amino acid region with homology to a DNA-binding motif of the high-mobility group (HMG) family of proteins (Fig. 48.3). When DNA encoding the HMG box was used to probe a genomic library, a subfamily of closely related genes was identified. Members of this family, defined as those encoding a region with 60% or greater amino acid similarity to the SRY HMG-box motif, are called *SOX* (SRY–box-related) genes (Goodfellow and Lovell-Badge, 1993).

locus, with the high-mobility group (HMG)-related box, DNA binding domain. Solid circles denote missense mutations that affect testicular development. Triangles indicate nonsense and frameshift mutations. (From Achermann JC, Hughes IA. Disorders of sex development. In: Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. *Williams textbook of endocrinology.* Philadelphia, PA: WB Saunders; 2011. Figure 23-21.)

Considerable evidence has accumulated that *SRY* is the TDF. In the mouse, expression of *Sry* correlates with testicular determination in the gonadal ridge (Koopman et al., 1990). *SRY* is an evolutionarily conserved gene on the Y chromosome of mammals. Chromosomal fragments related to *SRY* (i.e., the *SOX* genes) are very much conserved evolutionarily, being demonstrated in various vertebrates and marsupials. ***SRY* is localized to the smallest region of the Y chromosome capable of inducing testicular differentiation in humans and in mice** (Gubbay et al., 1992). In fact, Koopman et al. (1991) introduced into XX mouse embryos a 14-kb mouse genomic DNA fragment containing *Sry* and no other Y-linked gene sequences and demonstrated that it was capable of giving rise to normal testicular development in the transgenic mice. **The *SRY* protein functions as a transcription factor that, by binding and producing bending of the DNA, promotes protein-protein interaction and is able to activate downstream gene expression.** An expectation for TDF was that mutations in its protein sequence would result in sex reversal. Examination of the *SRY* sequence in XY females has identified more than 50 mutations in the protein-coding sequence, with the majority located within the DNA-binding domain. Another prediction for TDF is that its presence can cause XX male sex reversal. The majority of XX males to date have been found to contain Y chromosome segments containing *SRY*. This suggests a causative role of *SRY* in most cases of XX sex reversal. **Therefore, genetic and molecular data have established that *SRY* can be equated to the TDF.**

Additional insights have been gained regarding *SRY* function as a molecular switch that promotes testis development. *SRY* is expressed and functions in the supporting cells of the developing male urogenital ridge. These cells participate in cord formation and ultimately develop into Sertoli cells.

Key Points: Chromosomal Sex

- Sinclair et al. (1990) discovered the testis-determining factor (TDF), a single-copy male-specific sequence that was evolutionarily conserved.
- This gene was termed *SRY* (sex-determining region Y gene) in humans and *Sry* in mice.

Additional Genes Involved in Gonadal Determination

Several additional genes involved in gonadal development have been identified and characterized. These include, but are not limited to, *WT1*, *NR5A1(SF1)*, *SOX9*, *NR0B1(DAX1)*, *WNT4*, *RSPO1*, and *FOXL2* (Fig. 48.4; Table 48.1). Newer data suggest that these factors function in defined but interrelated differentiation pathways during gonadal formation and determination.

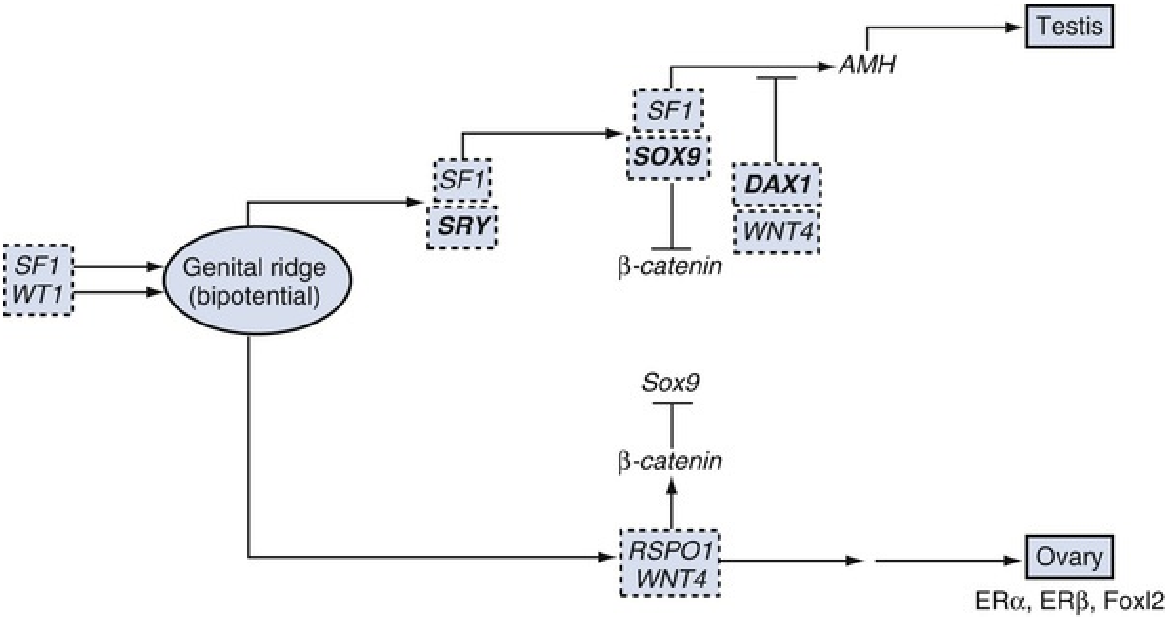

FIG. 48.4 Genes determining testis or ovarian differentiation from bipotential gonad. *SF1* and *WT1* are essential for gonadal ridge formation and development. Gonadal determination is influenced by transient expression of the testis determination factor, SRY. SOX9 upregulation by SRY leads to testis formation. Repression of SOX9, by factors such as DAX1 and WNT4/β-catenin, results in inhibition of testis formation and promotion of ovarian development. (From Hughes IA. Intersex. BJU Int 2002;90:771; and Sekido R, Lovell-Badge R. Sex determination and SRY: down to a wink and a nudge? *Trends Genet.* 2009;25[1]:19–29.)

FOXL2	3q23		Female; blepharophimosis-ptosis-epicanthus inversus syndrome (BPES); premature ovarian failure (BPES, type II)

WT1.

The *WT1* gene was originally isolated in cloning experiments that identified an oncogene on human chromosome 11 as being involved in the etiology of Wilms tumor (Call et al., 1990). This gene, originally localized by examining chromosomal deletions in children with WAGR syndrome (*W*ilms tumor, *A*niridia, *G*enitourinary abnormalities, gonadoblastoma, and mental *R*etardation), was found to be expressed primarily in the kidney and gonads of the developing human embryo (Kreidberg et al., 1993). The first reported mutations in Denys-Drash syndrome, which includes Wilms tumor, renal failure, and gonadal and genital abnormalities, were found to involve the WT1 protein (Pelletier et al., 1991a, 1991b). Indeed, mutations involving *WT1* have been found responsible for both the Frasier and Denys-Drash syndromes and manifest as a spectrum of genetically induced abnormalities involving the gonads and kidneys, owing to the earlier involvement of *WT1* in the differentiation of both structures. Frasier syndrome is characterized by both gonadal dysgenesis and renal abnormalities that result in streak gonads and a nephrotic syndrome (MacLaughlin and Donahoe, 2004). If it occurs in the XY genotype, sex reversal results. As a result of alternative splicing of the *WT1* gene, patients with Frasier syndrome are not susceptible to Wilms tumor, whereas those with Denys-Drash syndrome are (Koziell and Grundy, 1999). In addition, with the Denys-Drash syndrome, gonads differentiate more completely than with Frasier syndrome. Research on *Wt1* in the mouse suggests that it exerts its effects upstream of *Sry* and is likely to be necessary for commitment and maintenance of gonadal tissue (Lim and Hawkins, 1998).

NR5A1 (SF1).

The *NR5A1* gene encodes nuclear receptor steroidogenic factor 1 (*SF1)*, which is expressed in all steroidogenic tissues, including adrenal cortex, testis (Leydig cells), ovarian theca, granulosa cells, and corpus luteum. *SF1* is a key regulator of enzymes involved in steroid production, including the sex hormones, and contributes to the regulation of pituitary gonadotropin expression (Parker et al., 2002). In addition, *SF1* appears to play a role in early gonadal development at multiple levels of the reproductive endocrine axis (Ingraham et al., 1994; Luo et al., 1994). ***SF1* also appears to act synergistically with *WT1* in the regulation of anti-müllerian hormone (AMH), also known as müllerian-inhibiting substance (MIS),** expression (Shen et al., 1994; Imbeaud et al., 1995; Nachtigal et al., 1998) and may regulate *DAX1* (Yu et al., 1998) and *SOX9* expression (Sekido and Lovell-Badge, 2008).

Recent studies have suggested an additional role for NR5A1 in DSD. 46,XY individuals with heterozygous *NR5A1* mutations may have varying levels of undervirilization and gonadal dysgenesis (Philibert et al., 2007). There are two case reports of heterozygous mutations resulting in a more severe phenotype of 46,XY DSD associated with gonadal dysgenesis and adrenal insufficiency (Achermann et al., 1999; Orekhova et al., 2018). More recently, whole-exome sequencing of 46,XY and 46,XX DSD patients without prior genetic diagnoses has revealed a role for NR5A1, resulting in more subtle phenotypes. In addition, mutation of *NR5A1* in 46,XX individuals may lead to testicular or ovotesticular DSD as a result of decreased inhibition of the male developmental pathway (Baetens et al., 2017; Swartz et al., 2017). These findings suggest a novel role for NR5A1 in ovarian determination. Heterozygous missense mutations in NR5A1 have also been associated with male infertility because of severe impairment in spermatogenesis (Ferlin et al., 2015; Bashamboo et al., 2010).

SOX9.

The *SOX9* gene was originally identified in patients with campomelic dysplasia, a congenital disease of bone and cartilage formation that is often associated with XY sex reversal (Wagner et al., 1994). **The *SOX9* gene is structurally quite similar to *SRY*, with a 71% sequence similarity of the high-mobility group (HMG) domain to that of *SRY*.** Expression of the gene in adults is greatest in the testes. **Interestingly, *SOX9* gene activity increases immediately after SRY expression, and cell lineage analyses show that SOX9 protein is expressed in cells determined to become Sertoli cells** (Sekido and Lovell-Badge, 2009). Transgenic expression of SOX9 during urogenital ridge development in 46,XX mice results in induction of testis development in the absence of SRY expression (Vidal et al., 2001). **Therefore, the *SOX9* gene is a key downstream effector of SRY action. The activity of SRY on *SOX9* is synergistic with the activity of an additional transcription factor, steroidogenic factor 1 (SF1), which is essential for gonadal and adrenal development** (Sekido and Lovell-Badge, 2008). **The role of *SOX9* in male gonadal determination is further highlighted by data from genotypic males with *SOX9* mutations (46,XY) that exhibit ovarian development and male-to-female sex reversal** (Foster et al., 1994; Wagner et al., 1994). *SOX9* also upregulates *AMH* gene expression (MacLaughlin and Donahoe, 2004).

More recent studies have reported that mutations in the regulatory region of SOX9 can result in 46,XX DSD or 46,XY DSD. Duplication of a key regulatory region upstream of SOX9 may induce testicular differentiation in 46,XX individuals (Huang et al., 1999; Benko et al., 2011; Hyon et al., 2015). Furthermore, deletions of a different SOX9 regulatory region can result in undervirilization and gonadal dysgenesis in 46,XY individuals (Bhagavath et al., 2014; Kim et al., 2015).

NR0B1 (DAX1) and Dosage-Sensitive Sex Reversal (DSS).

The first indication that an X-specific gene was involved in human sex determination was provided in 1978 with the identification of a family with an X-linked mode of inheritance of 46,XY gonadal dysgenesis. Subsequent studies of a number of sex-reversed subjects confirmed the presence of additional X chromosomal genetic material and a normal Y chromosome (Ogata et al., 1992). **This finding suggested that duplication of an X-specific gene causes XY sex reversal by expressing a double dose of a region normally subject to X inactivation. Screening of XY females with a normal *SRY* gene detected such a submicroscopic duplication, involving a 160-kb region designated as the dosage-sensitive sex reversal (DSS) critical region** (Bardoni et al., 1994). Parallel studies examining 46,XY males with gonadal dysgenesis, hypogonadotropic hypogonadism, and congenital adrenal hypoplasia resulted in the identification of a candidate gene, *NR0B1 (DAX1)*, within the DSS critical region (Muscatelli et al., 1994; Zanaria et al., 1994). Interestingly, *DAX1* can act to suppress or promote the testis determination pathway (Yu et al., 1998; Meeks et al., 2003). Although *DAX1* was initially believed to be the primary gene involved in DSS, several sex-reversed 46,XY patients have been identified with duplication of the DSS region in the absence of *DAX1* duplication, which suggests that the gene dosage effects of this region may be associated with an additional gene or genes (Zanaria et al., 1995).

WNT4.

WNT4 on chromosome 1p34 appears to be involved in müllerian duct regression and may also function by antagonizing SRY activity (Kim et al., 2006; Bernard and Harley, 2007). Early inactivation of *Wnt4* in mice causes failure of the formation of müllerian duct derivatives in both sexes. In addition, inactivation of *Wnt4* in female mice leads to wolffian duct development without testicular tissue formation and female external genitalia. *WNT4* is implicated in development and maintenance of the female phenotype in women by regulating müllerian duct development and ovarian steroidogenesis (Biason-Lauber et al, 2004). Missense mutations of *WNT4* have been reported in 46,XX DSD with abnormal development of müllerian structures and variable degrees of virilization (Biason-Lauber et al., 2004; Biason-Lauber et al., 2007; Philibert et al., 2008; Maimoun et al., 2011).

RSPO1.

RSPO1 (R-spondin1) belongs to a family of ligands that activate the Wnt and β-catenin signaling pathways. Expression of RSPO1 overlaps that of Wnt in many tissues and can synergize with Wnt by stabilizing cytoplasmic β-catenin. This gene was identified as a candidate gene in ovarian determination by linkage analysis of a large consanguineous Italian family with cosegregation of palmoplantar hyperkeratosis (PPK) trait and XX female-to-male sex reversal (Parma et al., 2006). A single nucleotide, frameshift mutation was found in affected individuals from the consanguineous family and deletion mutations in sporadic cases of PPK and XX sex reversal.

Normal Phenotypic Development

Gonadal Stage of Differentiation

During the first 6 weeks of embryonic development, the gonadal ridge, germ cells, internal ducts, and external genitalia are bipotential in both 46,XY and 46,XX embryos. Under the genetic influences of sex determination, the bipotential gonadal ridges differentiate into either ovaries or testes, and germ cells develop into either oocytes or spermatocytes. Primordial germ cells can be recognized in the third week of gestation on the posterior wall of the secondary yolk sac. **Migration of the germ cells begins in the fifth week of gestation from the dorsal wall of the yolk sac through the mesentery to the medial ventral aspect of the urogenital ridge** (DeFilici et al., 2013) (Fig. 48.5). This process is dependent on chemoattractants and cell adhesion molecules (Hughes, 2002). Overall, a population of 1000 to 2000 primordial germ cells reaches the gonadal blastema by the sixth week of gestation.

FIG. 48.5 Migration of primordial germ cells. At 3 weeks, primordial germ cells are being formed and migrate along the wall of the yolk sac to reach the caudal part of the fetus. By 5 weeks, they have reached the level of the gonadal ridge. (From DeFelici M. Origin, migration, and proliferation of human primordial germ cells. In: Coticchio G, Albertini DF, DeSantis L, eds. *Oogenesis.* London: Springer-Verlag; 2013. p. 21.)

Transformation of the germ cells into spermatogonia and oogonia results from differentiation of the epithelial gonadal compartments referred to as testicular and ovarian “cords.” ***SRY* initiates the switch that induces a cascade of genes directing the indifferent gonad toward testicular organogenesis.** The precise moment at which this occurs remains unknown. Initially, differentiation of Sertoli cells is noted as testicular cords form at 6 to 7 weeks’ gestation, creating the basement membrane, or blood-testis barrier, of spermatogonia and Sertoli cells on one side and mesenchymal fibroblasts on the other. **The differentiation of Sertoli cells is associated with the production of AMH (anti-Müllerian hormone), a glycoprotein encoded by a gene on the short arm of chromosome 19** (Haqq et al., 1994). In males, a second line of primordial cells of steroidogenic mesenchyme remain among the testicular cords and represent future Leydig cells, which differentiate at 8 to 9 weeks. **In the absence of *SRY,* ovarian organogenesis results.** Little is known about the genetic control of ovarian development. To date, no genes whose products direct development of the ovary have been identified. **It does appear necessary that there be duplicate copies of at least one X chromosomal locus (which presumably explains the dysgenetic ovaries in 45,XO Turner syndrome patients).** A potential candidate may lie within the DSS critical region on Xp-21, which, when duplicated, promotes male-to-female “sex reversal” (Bardoni et al., 1994; Lopez et al., 1998).

Unlike the testis, which functions primarily as a fetal endocrine organ, the ovary has primarily exocrine activity. In embryonal ovaries, germ cells undergo intense mitotic proliferation (preceding the onset of meiotic prophase) and in the process exhaust their entire mitotic potential prenatally, reaching a maximum endowment of 20 million cells by 20 weeks' gestation. The presence of two X chromosomes appears to be responsible for differentiation of the granulosa cells into the protective mantle of the granulosa layer and "rescue" of 30% of germ cells (approximately 2 million) (Byskov and Westergaard, 1998).

Key Point: Gonadal State of Differentiation

- During the first 6 weeks of embryonic development, the gonadal ridge, germ cells, internal ducts, and external genitalia are bipotential in both 46,XY and 46,XX embryos.

Gonadal Function

Testis

The initial endocrine function of the fetal testes is the secretion of AMH by the Sertoli cells at 7 to 8 weeks' gestation. AMH, one of the two hormones necessary for male sexual differentiation, acts locally to produce müllerian regression. It is a member of the transforming growth factor-β (TGF-β) family, and the human gene has been cloned and mapped to chromosome 19 (Cate et al., 1986). Little is known about the cellular mechanism of action of AMH. Because the hallmark of AMH-mediated müllerian duct regression is the formation of a ring of connective tissue around the epithelial cells, it is likely that the mesenchyme is the primary target of AMH. **Testosterone secretion by the fetal testes is detectable shortly after the formation of Leydig cells in the interstitium at approximately 9 weeks' gestation** (Siiteri and Wilson, 1974). There is a rise in serum and testicular testosterone to a peak concentration at 13 weeks and then a decline. The rate-limiting enzyme for fetal testosterone synthesis is 3β-hydroxysteroid dehydrogenase, which is approximately 50 times more highly concentrated in the fetal testes than in the ovary. Androgens are synthesized by the Leydig cells, initially autonomously, but then dependent on placental human chorionic gonadotropin (hCG) secretion. Later in gestation, with declining hCG concentrations, androgen synthesis is controlled by luteinizing hormone (LH) secretion by the fetal pituitary gland. **Jost et al.** (1973) **clearly demonstrated that androgen is essential for virilization of wolffian duct structures, the urogenital sinus, and the genital tubercle. Testosterone, the major androgen secreted by the testes, enters target tissues by passive diffusion.** Organs such as the wolffian duct, adjacent to the fetal testis, also take up testosterone by pinocytosis. **The local source of androgen is important for wolffian duct development, which does not occur if testosterone is supplied only via the peripheral circulation. In some cells, such as those in the urogenital sinus, testosterone is converted to dihydrotestosterone (DHT) by intracellular 5α-reductase.** Testosterone or DHT then binds to a high-affinity intracellular receptor protein, and this complex enters the nucleus, where it binds to acceptor sites on DNA, resulting in new messenger RNA and protein synthesis (Fig. 48.6). The androgen receptor has been characterized as a high-affinity receptor that mediates the action of testosterone and DHT in all androgen-dependent tissues. In disorders of the androgen receptor, such as androgen insensitivity syndrome, testosterone production is normal, but the hormone is unable to reach the nucleus and interact with DNA. Various defects in the androgen receptor result in a spectrum of phenotypic abnormalities in the genetic male. Because gonadal females have androgen receptor within their tissues, exogenous androgen produces virilization. **DHT binds to the androgen receptor with greater affinity and stability than does testosterone. Therefore, in tissues equipped with 5α-reductase at the time of sexual differentiation (e.g., prostate, urogenital sinus, external genitalia), DHT is the active androgen** (George and Peterson, 1988). The 5α-reductase activity has two optimal pH values in cultured genital skin fibroblasts—one at pH 5.5 and a second one near pH 8—that correspond to two distinct enzymes (Jenkins et al., 1992). The alkaline enzyme, human steroid 5α-reductase type 1, was cloned first; however, the primary enzyme in the prostate is 5α-reductase type 2 (Andersson and Russell, 1990). A deletion in the gene coding for this enzyme has been discovered in DSD patients with 5α-reductase deficiency (Andersson et al., 1991). The gene encoding the androgen receptor has been cloned and mapped to the X chromosome at Xq11–12 (Lubahn et al., 1988).

FIG. 48.6 Schematic diagram of normal androgen physiology. The major actions of androgens are listed on the right. Testosterone enters androgen target tissues and either binds to the androgen receptor in cell nuclei or is converted by 5α-reductase to dihydrotestosterone (DHT). DHT binds to the same receptor but with greater affinity. Androgen actions mediated by testosterone are indicated by *solid arrows,* and those mediated by DHT are indicated by *dashed arrows.* (From Griffin JE, Wilson JD. Syndromes of androgen resistance. *Hosp Pract.* 1987;22:99–114.)

Key Point: Gonadal Function

- DHT binds to the androgen receptor with greater affinity and stability than does testosterone. Therefore in tissues equipped with 5α-reductase at the time of sexual differentiation (e.g., prostate, urogenital sinus, external genitalia), DHT is the active androgen.

Ovary

Estrogen synthesis is detectable in the female embryo just after 8 weeks' gestation. The rate-limiting enzyme is aromatase, which is higher in the fetal ovary than in the fetal testis. Estrogens are not required for normal female differentiation of the reproductive tract, but they can interfere with male differentiation. Estrogen can block the effect of AMH on müllerian ducts, and prenatal estrogen treatment of mothers has been associated with male reproductive tract abnormalities (Gill et al., 1979; Vigier et al., 1989).

Phenotypic Sexual Development

Before the eighth week of gestation, the urogenital tract is identical in the two sexes. Both the wolffian and the müllerian duct systems are present as anlagen of the internal accessory organs of reproduction (Fig. 48.7). In addition, at this stage, the anlagen of the external genitalia of male and female embryos are indistinguishable (Fig. 48.8). **In the male fetus, Sertoli cells produce AMH, which acts locally and unilaterally to suppress the müllerian ducts, and Leydig cells produce testosterone, which permits local development of the wolffian ducts.** By 10 weeks' gestation, degeneration of the müllerian ducts is almost complete, and the wolffian ducts have become more prominent (see Fig. 48.7). Adjacent to the testes, convolutions of the ducts organize to form the epididymis. The wolffian ducts of the epididymis join with the collecting portion of the testicular tubules (rete testes). Distally, the ducts join the urogenital sinus by about 30 days' gestation, where they develop into the seminal vesicles. In the female fetus, testosterone is not secreted by the ovaries, and therefore the wolffian ducts regress. Because the ovary does not produce AMH, the müllerian ducts are maintained and develop into the female internal reproductive tract. The cephalic ends are anlagen of the fallopian tubes, and the caudal ends fuse to form the uterus (see Fig. 48.7). Contact of the müllerian ducts with the urogenital sinus induces formation of the uterovaginal plate, which ultimately forms the lumen of the vagina. The relative contributions of the müllerian ducts and urogenital sinus to the formation of the vagina remain somewhat controversial; however, there is some agreement that the proximal two-thirds of the vagina is contributed by the müllerian ducts and the distal one-third by the urogenital sinus. Masculinization of the male fetus starts between 7 and 8 weeks' gestation (Fig. 48.9). The first sign of male phenotypic differentiation is degeneration of the müllerian ducts adjacent to the testes as a result of AMH secretion by the Sertoli cells. Whereas the effects of androgen on the wolffian ducts are related to diffusion of testosterone from the adjacent gonad, masculinization of the external genitalia results from the systemic delivery of testosterone with local conversion to dihydrotestosterone. By 10 weeks' gestation, an increase in distance between genital tubercle and anal folds can be seen. The genital tubercle thickens and elongates to become the penis, and the urethral folds fuse from posterior to anterior over the urethral groove (Fig. 48.10). Near the bladder, the urethra is surrounded by the prostate. The urogenital swellings migrate posteriorly to the genital tubercle and fuse to form the scrotum. **By 12 to 13 weeks' gestation, the**

genitalia of the male fetus are completed with closure of the elongated urogenital cleft. Under the influence of androgen secreted by the fetal testes, penile growth and testicular descent occur in the third trimester (see Fig. 48.9). In the female fetus, the absence of circulating testosterone maintains the appearance of the external genitalia at the 6-week gestational stage. The genital tubercle develops only slightly to form the clitoris. The lateral genital swellings become the labia majora, and the adjacent urethral folds become the labia minora (Fig. 48.11). Between the labia minora will develop the vaginal introitus and urethral meatus.

Gender Identity, Gender Role, and Gender Orientation

Psychosexual Development

Humans have been recognized as having sexually dimorphic behavior, which has several aspects: (1) *gender identity,* the identification of self as either male or female; (2) *gender role,* aspects of behavior in which males and females appear to differ; (3) *gender orientation,* or choice of sexual partner (heterosexual, homosexual, or bisexual); and (4) *cognitive differences* (Grumbach and Conte, 1998). Gender identity is a complex and poorly understood phenomenon in humans, and the mechanisms appear multifactorial. Experience in patients with congenital adrenal hyperplasia (CAH) who were exposed prenatally to androgen and in patients reared in a sex opposite to their chromosomal or gonadal sex have provided evidence to indicate that gender identity is not merely a function of chromosomal complement or prenatal endocrine milieu. Postnatal environmental factors and learning appear to have an important effect. However, strong evidence has accumulated for the impact of prenatal hormonal influences on sexually dimorphic behavior or gender role. For example, long-term follow-up with CAH patients has supported a greater interest in “tomboyish behavior” than in unaffected girls, although these patterns are not abnormal in relation to female behavior in Western society (Ehrhardt and Meyer-Bahlburg, 1981). Additional information regarding the influence of androgens on gender identity and gender role has arisen from one study of males with cloacal exstrophy who underwent gender reassignment within the first few months of life. A majority of these patients had behaviors and attitudes that reflected strong male-typical characteristics regardless of whether they were raised as males or females (Reiner and Gearhart, 2004). However, a subsequent British study of a similar 46,XY cloacal exstrophy cohort presented contradictory findings (Baker Towell and Towell, 2003). The previously accepted dogma that children are psychosexually neutral at birth and capable of being environmentally oriented (the blue room/pink room theory) has been seriously challenged by those who support the concept of prenatal psychosexual differentiation (Money and Ehrhardt, 1972; Diamond and Sigmundson, 1997). Support for either theory in humans is based on the assessment of a limited number of affected patients. An improved understanding of the “nature versus nurture” controversy will probably prove important in the optimal management of patients with DSDs. However, our increased awareness of physiologically normal patients with genuine “gender dysphoria” has illustrated the complexity of this process and the fluidity of gender that challenges long-held concepts of binary behavior.

Key Point: Psychosexual Development

- The previously accepted dogma that children are psychosexually neutral at birth and capable of being environmentally oriented (the blue room/pink room theory) has been seriously challenged by those who support the concept of prenatal psychosexual differentiation.

Abnormal Sexual Development

The classification of DSDs (previously “intersex disorders”) has undergone evolutionary change as understanding of the etiologic mechanisms of normal and abnormal sexual development has improved. As a result, classification systems vary. The authors have borrowed from the system used by Grumbach and Conte (1998), which incorporates the historical emphasis on classification by gonadal morphology and introduced more contemporary terminology (Hughes et al., 2006). Descriptive terms for abnormal gonadal histology have been retained, with the exception of *true hermaphroditism*, which has been replaced by *ovotesticular DSD*. But, for masculinized 46,XX females with two ovaries, *female pseudohermaphroditism* has been replaced by 46,XX DSD. And, for undermasculinized 46,XY males, the term *male pseudohermaphroditism* has been replaced by 46,XY DSD. The first category includes disorders of gonadal differentiation, the second includes ovotesticular DSD, the third includes 46,XX DSD (the masculinized female, that is, ovaries present but external genitalia exhibiting evidence of masculinization), the fourth includes 46,XY DSD (the undermasculinized male, that is, testes present but genital ducts and/or external genitalia incompletely masculinized), and the fifth category includes unclassified forms. Within each category, remarkable advances in chromosomal and biochemical information have allowed subclassification of disorders based on etiologic mechanisms, contributing to a more rational classification system (Table 48.2).

TABLE 48.2

Abnormal Sexual Differentiation

1. Disorders of Gonadal Differentiation

Seminiferous tubule dysgenesis
Klinefelter syndrome
46,XX male
Syndromes of gonadal dysgenesis
    Turner syndrome

    Mixed gonadal dysgenesis
    Partial gonadal dysgenesis (dysgenetic male pseudohermaphroditism)
    Bilateral vanishing testis/testicular regression syndromes

2. Ovotesticular DSD (True Hermaphroditism)
3. 46,XX DSD (Masculinized Female)
Congenital adrenal hyperplasia (21-hydroxylase, 11β-hydroxylase, 3β-hydroxysteroid dehydrogenase deficiencies) Maternal androgens
4. 46,XY DSD (Undermasculinized Male)
Leydig cell agenesis, unresponsiveness Disorders of testosterone biosynthesis Variants of congenital adrenal hyperplasia affecting corticosteroid and testosterone synthesis StAR deficiency (congenital lipoid adrenal hyperplasia) Cytochrome P450 oxidoreductase (POR) deficiency 3β-Hydroxysteroid dehydrogenase deficiency 17β-Hydroxylase deficiency Disorders of testosterone biosynthesis 17,20-Lyase deficiency 17β-Hydroxysteroid oxidoreductase deficiency Disorders of androgen-dependent target tissue Androgen receptor and postreceptor defects Syndrome of complete (severe) androgen insensitivity Syndrome of partial androgen insensitivity Mild androgen insensitivity syndrome (MAIS) Disorders of testosterone metabolism by peripheral tissues 5α-Reductase deficiency Disorders of synthesis, secretion, or response to müllerian-inhibiting substance Persistent müllerian duct syndrome
5. Unclassified Forms
In females Mayer-Rokitansky-Küster-Hauser syndrome

Evaluation and Management of the Newborn With Ambiguous Genitalia

The evaluation and initial management of the neonate with ambiguous genitalia must be regarded as a medical and psychosocial emergency and be handled with great sensitivity toward the family. Ideally, a medical team including a pediatric urologist, an endocrinologist, a geneticist, and a psychiatrist or psychologist experienced in managing DSD patients should work closely with the family. **The team's goal should be to make a precise diagnosis of the disorder (which can be achieved in most cases) and, with the involvement of the parents, to assign a proper sex of rearing based on the diagnosis, the status of the child's anatomy, and the functional potential of the genitalia and reproductive tract.**

In obtaining the history, certain pieces of information may be particularly valuable. A history of infant death within the family might suggest the possibility of CAH, and infertility, amenorrhea, or hirsutism might also suggest possible familial patterns of DSD states. Certainly, maternal use of medications, in particular steroids or contraceptives, during the pregnancy is of great importance.

One critical finding on physical examination is the presence or absence of gonads. Bilateral nonpalpable gonads with ambiguous genitalia is suspicious for virilization of a female secondary to CAH. The ability to palpate one or two gonads effectively rules out overmasculinization of the female. Because ovaries do not descend, a distinctly palpable gonad along the pathway of descent is highly suggestive of a testis. Rarely, an ovotestis undergoes descent to the inguinal canal and may be suspected on the basis of asymmetry of tissue texture of the poles of the gonad. This suspicion may be further supported by ultrasound findings. **The patient with bilaterally impalpable testes or a unilaterally impalpable testis and hypospadias should be regarded as having a DSD until proven otherwise, whether or not the genitalia appear ambiguous.** Kaefer et al. (1999) studied the incidence of DSDs in patients with cryptorchidism and hypospadias and without ambiguous genitalia. **With both unilateral and bilateral cryptorchidism, and hypospadias, the incidence of DSD was 30% overall. The incidence was approximately 15% if an undescended testis was palpable and 50% if it was impalpable.** In addition, posterior urethral meatal position was noted to be a strong predictor of DSD in this group of patients—65%, versus 5% to 8% with a midshaft to anteriorly located hypospadiac meatus (Kaefer et al., 1999).

In addition to gonadal examination, penile size should be assessed and an accurate measure of stretched penile length recorded. The mean stretched penile length in full-term males born in the United States is 3.5 cm (± 0.04) (Lee et al., 2006). The location of the urethral meatus versus a single perineal opening should be identified and documented. Measurement of the anogenital distance (AGD) may serve as an indicator of fetal androgen exposure and has been found to correlate with testis size, sperm count, penis length, and testosterone levels in rats and humans (Dean et al, 2013). However, AGD is not widely used because of the lack of normative values. Another means to document the degree of virilization is the External Masculinization Score (EMS). Scoring is based on individual features of the external genitalia (phallus size, labioscrotal fusion, gonad location, and location of urethral meatus) (Ahmed et al., 2011). The utility of this instrument in predicting clinical outcomes has not been demonstrated thus far.

An additional important finding on physical examination is the presence of a uterus, which is noted as an anterior midline cordlike structure on rectal examination. **A more precise means of assessing müllerian anatomy is by pelvic ultrasonography, which may be performed immediately in the neonatal period.** In addition to defining müllerian anatomy and confirming the presence or absence of a uterus, the gonads and adrenal glands should be studied. Normal anatomy of an undescended gonad should be confirmed, and a cyst within the gonad, consistent with ovotestis, should be ruled out.

Within the immediate neonatal period, a karyotype should be obtained. Typically this requires 2 days to perform. Therefore, an attractive approach to obtain chromosomal data quickly is fluorescence in-situ hybridization, which rapidly identifies X and Y chromosomes. It is typically used to confirm the presence of a second X chromosome. The technique is much more rapid than karyotyping, producing results within a few hours.

Serum studies should be immediately sent to rule out a salt-wasting form of CAH. In addition to serum electrolytes, testosterone and DHT should be measured early. Migeon et al. (1994) emphasized that the androgen levels may drop quickly, necessitating early study. In addition, they suggested that serum 17-hydroxyprogesterone should not be measured until day 3 or 4 to rule out 21-hydroxylase deficiency, because the stress of delivery may result in physiologic elevation of this steroid precursor in the first 1 or 2 days of life.

In the absence of palpable testes, the presence or absence of testicular tissue should be determined by documentation of a markedly elevated LH during mini-puberty, consistent with anorchia, or by means of an hCG stimulation test, which can demonstrate normally functioning testicular tissue (Jarow et al., 1986). In addition to ruling out anorchia, the study can enable diagnosis of 5α-reductase deficiency (by virtue of an increased ratio of testosterone to DHT) and can help distinguish between impaired testosterone synthesis (deficient response to hCG) and androgen insensitivity (normal response to hCG). Serum AMH measurement has been proposed as a reliable marker of the presence of testes (Hughes, 2002).

Key Points: Evaluation and Management of DSD

- The team's goal should be to make a precise diagnosis of the disorder (which can be achieved in most cases) and, with the involvement of the parents, to assign a proper sex of rearing based on the diagnosis, the status of the child's anatomy, and the functional potential of the genitalia and reproductive tract.
- The patient with bilaterally impalpable testes or a unilaterally impalpable testis and hypospadias should be regarded as having a DSD until proven otherwise, whether or not the genitalia appear ambiguous.

Based on physical examination (largely, gonadal palpability), the presence or absence of müllerian structures on ultrasonography, 17-hydroxyprogesterone concentration, and the karyotype, a reasonable differential diagnosis may be formulated (Fig. 48.12). A precise diagnosis can virtually always be achieved for the 46,XX DSD (overvirilized female) but in less than 50% of 46,XY DSD undervirilized males (Lee et al, 2006). The presence of asymmetrical anatomy on examination and ultrasonography is an important observation and suggests mixed gonadal dysgenesis if the karyotype is XY and ovotesticular DSD if it is 46,XX (Fig. 48.13).

Laparotomy or laparoscopy and gonadal biopsy is usually the next definitive clinical step required when a firm diagnosis based on the aforementioned data is impossible. **Laparotomy or laparoscopy in this setting remains a diagnostic maneuver; removal of gonads or reproductive organs should be deferred**

until the final pathology report is available and a gender has been assigned. Polymerase chain reaction (PCR) characterization of the androgen receptor in venous blood DNA may define the precise genetic abnormality responsible for a given DSD, be it an abnormal androgen receptor or an enzyme abnormality. These studies should be performed in specialized laboratories where normal values are well established.

Finally, anatomic definition of the urogenital sinus and ductal structures contributes to the correct diagnosis and is necessary before any surgical intervention. The urogenital sinus is well imaged by retrograde contrast injection, which also opacifies ductal structures, defines the entry of urethra and vagina into the sinus, and outlines the cervical impression within the vagina. Endoscopy can define these relationships further but is usually not necessary until surgical reconstruction becomes imminent.

Gender Assignment

After a definitive diagnosis has been reached, a thorough and candid discussion with the family regarding gender assignment should take place. **Issues related to the diagnosis-specific potential for normal sexual functioning and fertility and the risk for gonadal malignancy should be addressed.** Parents should understand that high-quality data regarding the long-term psychosocial outcomes of gender assignment for the majority of DSDs are lacking, although longitudinal studies are being pursued. Parental involvement in the decision-making process is essential. If the diagnosis of a DSD is made prenatally, it is important to present a plan of management to the parents or risk termination of the pregnancy (Nihoul-Fekete, 2004).

In the setting of a 46,XX karyotype and masculinized female, gender assignment is usually appropriately female. In CAH, cortisol suppresses the undesired androgen; and if maternal androgen is responsible for virilization, its discontinued stimulation is corrective. In both cases, there are normal ovaries and müllerian ducts, and a normal reproductive potential exists. **If the karyotype is 46,XY, the issue is a more complex one and includes factors such as penile length and evidence of androgen insensitivity.** For example, 46,XY patients with complete (severe) androgen insensitivity are appropriately assigned a female gender, whereas those with 5α-reductase deficiency may be more appropriately assigned a male gender. The most frequent abnormal karyotype is 45,X/46,XY mosaicism, which presents a variable phenotypic spectrum. The degree of masculinization of the external genitalia appears to vary with the amount of testicular tissue present, and gender assignment depends on the functional potential of the gonadal tissue, reproductive tracts, and genitalia. The best predictor of adult gender identity is initial gender assignment (Cohen-Kettenis, 2005). Some investigators have suggested deferring the issue of gender assignment until patients reach an age at which they may declare their own gender identity. Such an approach, although rational, is difficult to implement given cultural norms and not recommended in the consensus statement (Lee et al., 2006). As Elliott (1998) states, "We treat these children the way we do (as male or female) because this is the way we see the world; most importantly it is the way that the children, themselves, are taught to see the world."

Overall, it is well to remember in the management of ambiguous genitalia the parameters of optimal gender policy outlined by Meyer-Bahlburg (1998):

- **Reproductive potential (if attainable at all)**
- **Good sexual function**
- **Minimal medical procedures**
- **An overall gender-appropriate appearance**
- **A stable gender identity**
- **Psychosocial well-being**

Disorders of Gonadal Differentiation and Development

Klinefelter Syndrome and Variants

In 1942, Klinefelter, Reifenstein, and Albright described a syndrome characterized by eunuchoidism, gynecomastia, azoospermia, increased gonadotropin levels, and small, firm testes. By 1959, these patients were noted to have a 47,XXY karyotype (Jacobs and Strong, 1959).

Klinefelter syndrome represents the most common major abnormality of sexual development. By definition, males with at least one Y chromosome and at least two X chromosomes have Klinefelter syndrome. The classic 47,XXY complement arises as a result of nondisjunction during meiosis; it occurs in 1 of 600 liveborn males (Morris et al, 2008). But the phenotype is also associated with 48,XXYY and 49,XXXYY, and an exaggerated form of the phenotype is associated with 48,XXXY and 49,XXXXY. The mosaic form 46,XY/47,XXY is associated with milder phenotypic features of classic 47,XXY Klinefelter syndrome. Perhaps as a result of phenotypic variability, Klinefelter syndrome is believed to be underdiagnosed, with a 25% diagnostic rate in one Danish study (Bojesen et al, 2003).

In 47,XXY adults, seminiferous tubules degenerate and are replaced with hyaline. As a result, testes are firm and small, less than 3.5 cm in length. Histologically, Leydig cells appear to predominate. They are seen in large clumps in certain areas of the testes, sometimes resembling Leydig cell tumors. However, the absolute volume of Leydig cells is not increased and is probably lower than normal. Serum levels of testosterone are low-normal and those of gonadotropins are elevated. Plasma estradiol levels tend to be high, with gynecomastia the result of an increased ratio of estradiol to testosterone. The vast majority of patients are azoospermic, and the presence of sperm suggests 46,XY/47,XXY mosaicism. There does appear to be a depletion of germ cells with the onset of puberty (Wikström et al., 2004). Fertility, with the benefit of testicular sperm extraction and intracytoplasmic sperm injection (ICSI), has been reported in patients with Klinefelter syndrome. A recent meta-analysis examining ICSI outcomes reported a 43% live birth rate per ICSI cycle (Corona et al., 2017). Some infertility experts advocate coupling intracytoplasmic sperm injection with preimplantation diagnosis given the lower rate of normal embryos from Klinefelter syndrome patients (54%) versus controls (77%) (Staessen et al, 2003). However, there have been over 200 normal live births reported using ICSI without preimplantation genetic analysis, which brings into question the utility of this testing in predicting outcomes (Ni et al., 2016).

The decreased androgen production may impair normal secondary sexual development. Muscle development may be poor, and the fat distribution is more typical of females than of males. Normal amounts of pubic and axillary hair may be present, but facial hair is sparse. Patients tend to be taller than average, mainly because of the disproportionate length of their legs, which is present even in childhood. Otherwise, few if any distinguishing features are present in the prepubertal child.

Gynecomastia, which can be quite marked, is a common pubertal development in patients with Klinefelter syndrome. As a result, these patients have eight times the risk for development of breast carcinoma compared with normal males (Harnden et al., 1971). In addition, they are predisposed to developing malignant neoplasms of extragonadal germ cell origin as well as Leydig and Sertoli cell tumors (Völkl et al., 2006). Routine testicular examinations for postpubertal patients with Klinefelter syndrome is recommended.

An intriguing area of research has been in the neuropsychiatric function of Klinefelter syndrome patients. Studies have demonstrated depressed verbal ability and limitations in frontal executive functioning. Neuroimaging studies have shown selective volume differences in corresponding areas of Klinefelter syndrome patients' brains versus normal subjects (Giedd et al., 2007). Other studies have demonstrated altered cerebral perfusion in Klinefelter syndrome, corresponding to impaired verbal skills (Itti et al., 2003).

Management of Klinefelter syndrome entails careful androgen supplementation in selected male patients to improve libido and reduction mammoplasty if necessary. Surveillance for testicular tumor and breast carcinoma is also appropriate. Assisted reproductive techniques now offer potential fertility to nonmosaic Klinefelter syndrome patients. Microdissection testicular sperm extraction (micro-TESE) results in sperm retrieval rates in the 40% to 50% range, with higher rates in younger men (Bryson et al., 2014). Research studies have determined that sperm retrieval rates in adolescent males are comparable to adults (Plotton et al., 2015; Nahata and Yu et al., 2016).

46,XX Males

The condition of 46,XX maleness, which occurs in 1 of 20,000 males, may be closely related to that of Klinefelter syndrome. Historically, the genetic analysis of subjects with sex reversal who had a phenotypic sex different from that anticipated based on karyotype was crucial for identification of the *SRY* gene.

XX maleness, first recognized by de la Chappelle et al. in 1964, is characterized by testicular development in subjects who have two X chromosomes and lack a normal Y chromosome. Most of these subjects have normal male external genitalia, but 10% have hypospadias, and all are infertile.

Two categories of patients with XX maleness have been identified: 80% are *SRY* positive and 20% are *SRY* negative (Andersson et al., 1986; Zenteno-Ruiz et al., 2001; Ono et al., 2013). The *SRY*-positive group rarely have genital abnormalities, but they have phenotypic features of Klinefelter syndrome, including hypogonadism, gynecomastia, azoospermia, and hyalinization of seminiferous tubules with altered hormonal levels at puberty (low testosterone, increased follicle-stimulating hormone [FSH] and LH) (Fechner et al., 1993). Often, the diagnosis is made in a pubertal male who presents for evaluation of gynecomastia. **These patients differ from those with Klinefelter syndrome in that they are shorter (mean height, 168 cm) and have normal skeletal proportions.** XX males with no detectable *SRY* more commonly have genital ambiguity.

Several mechanisms have been proposed to explain XX sex reversal. **The most common is translocation of Y chromosomal material, including *SRY,* to the X chromosome**. Clearly, this can be proven in the majority of patients. Alternatively, sex reversal could result either from the mutation of an autosomal or X chromosomal gene, permitting testicular differentiation downstream from *SRY,* or from undetected mosaicism with a Y-bearing cell line. Clinical studies have demonstrated XX sex reversal to be a genetically and phenotypically heterogeneous condition (Fechner et al., 1993). Recently, Bashamboo et al. reported on 46,XX children and adults from four families with varying degrees of testis development and suggest that heterozygous missense mutations in *NR5A1* may alter organ fate from ovary to testis (Bashamboo et al., 2016).

Treatment of XX maleness is similar to that for Klinefelter syndrome. Androgen replacement benefits selected patients, and reduction mammoplasty may be beneficial. It is likely that these patients will also be at increased risk for breast carcinoma and testis tumor. Because of their lack of germ cell elements, those classic patients presenting with infertility would not benefit from testicular biopsy for potential intracytoplasmic sperm injection.

Syndromes of Gonadal Dysgenesis

Turner Syndrome.

In 1938, Henry Turner described the combination of sexual infantilism, webbed neck, and cubitus valgus (increased carrying angle at the elbows) as a distinct entity. Subsequently, gonadal dysgenesis was recognized as part of this syndrome (Hall and Gilchrist, 1990). It was not until 1959 that Ford recognized that one missing X chromosome was the etiologic basis for the syndrome. Subsequent chromosomal studies showed that **Turner syndrome is characterized by the presence of only one normally functioning X chromosome** (Ford et al., 1959). The other sex chromosome may be absent or abnormal, or mosaicism may be present.

Turner syndrome, with a 45,X karyotype, is associated with four classic features: female phenotype, short stature, lack of secondary sexual characteristics, and a variety of somatic abnormalities. But the clinical features of Turner syndrome are quite variable, and almost any combination of physical features may be seen with any X chromosomal abnormality. The severity of phenotypic features does not necessarily correlate with karyotypic findings. The diagnosis of Turner syndrome should be considered in any infant with lymphedema or any young woman with short stature or primary amenorrhea. Deletions in the short stature homeobox *(SHOX)* gene located on the pseudoautosomal region of the X and Y chromosomes have been suggested as the basis for the short stature in this syndrome.

Turner syndrome has an incidence of 1 in 2500 live births. One-half of the patients have a 45,X karyotype in all cells; this is believed to be secondary to loss of an X chromosome through nondisjunction in gametogenesis or an error in mitosis. From 12% to 20% of patients with Turner syndrome have an isochrome X (duplication of one arm of the X chromosome with loss of the other arm). Mosaicism—the presence of two or more chromosomally different cell lines—occurs in 30% to 40% of these patients, the majority (10% to 15%) being 45,X/46,XX and 2% to 5% being 45,X/46,XY (Zinn et al, 1993). **The presence of Y chromosomal material is of critical importance in patients with Turner syndrome because it predisposes them to potential masculinization and gonadoblastoma (Fig. 48.14).**

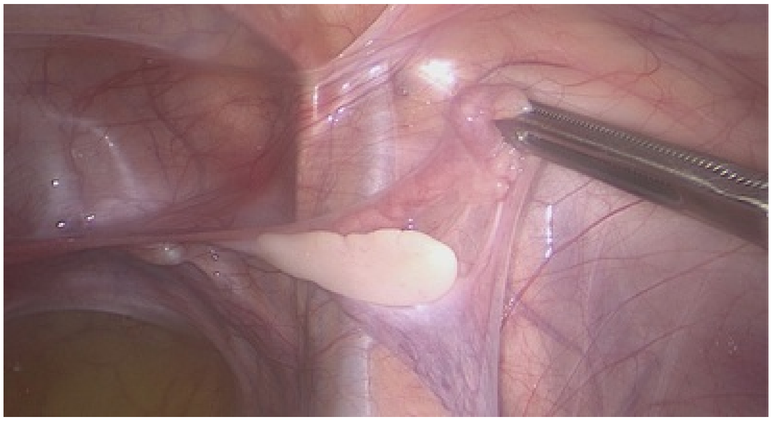

FIG. 48.14 Gross appearance of streak gonad during diagnostic laparoscopy. (Courtesy of D. Diamond, MD.)

Turner syndrome may be diagnosed prenatally on the basis of a variety of ultrasound findings (increased nuchal translucency, lymphedema, cystic hygroma, coarctation of the aorta, renal anomalies) or by abnormal results of fetal karyotyping. Affected fetuses often abort spontaneously. Whereas a 45,X fetus identified prenatally has a prognosis similar to that of a child with Turner syndrome diagnosed postnatally, approximately 90% of fetuses in whom a 45,X/46,XX or 45,X/46,XY karyotype is incidentally diagnosed prenatally will have a normal female or male phenotype at birth. This so-called *ascertainment bias* in Turner syndrome has profound implications for prenatal counseling.

It is postulated that in Turner syndrome, follicular cells that normally surround the germ cells and provide a protective mantle for the oocytes are inadequate (Stanhope et al, 1992). As a result, the rate of attrition of oocytes caused by apoptosis is so rapid that by birth few or no oocytes remain in the **ovaries, which become streaks** (Epstein, 1990). Typically, these streaks are white, fibrous structures, 2 to 3 cm long and approximately 0.5 cm wide, located in the broad ligament. Histologically, the streak possesses interlacing waves of dense fibrous stroma that is devoid of oocytes but is otherwise indistinguishable from normal ovarian stroma. Both estrogen and androgen are decreased, and levels of FSH and LH are increased. Secondary sexual development does not occur in the majority of patients. Pubic and axillary hair fails to develop in normal abundance, and the well-differentiated external genitalia, vagina and müllerian derivatives, and breasts remain small (Saenger, 1996). Turner syndrome is a common cause of primary amenorrhea, and the diagnosis is frequently made because pubertal development never occurs. Spontaneous pubertal development may occur in up to 30% of Turner syndrome patients, however.

The associated congenital anomalies that are thought typical in Turner syndrome include short stature, broad chest, widespread nipples, webbing of the neck, peripheral edema at birth, short fourth metacarpal, hypoplastic nails, multiple pigmented nevi, coarctation of the aorta, bicuspid aortic valve, and renal anomalies, but there is phenotypic variability (Fig. 48.15) (Miguel-Neto et al., 2016). The majority of the associated congenital anomalies can be explained by the presence of lymphedema at critical points in development, leading to an imbalance in growth forces. This may be secondary to failed opening of embryonic lymphatic channels (Zinn et al., 1993).

FIG. 48.15 Patient with Turner syndrome as originally described by Ullrich in 1930. (From Ullrich O. *Über typische Kombinationsbilder multipler Abartungen.* Z Kinderheilkd 1930;49:271–276.)

Of paramount importance in the assessment of the patient with Turner syndrome is identification of Y chromosomal material or 45,X/46,XY mosaicism, whose detection has been enhanced by use of the PCR (Bianco et al, 2006). **In patients with occult Y chromosomal material, the risk for gonadoblastoma, an in-situ germ cell cancer, is 12% to 20% and is being further defined** (Kwon et al, 2017; Schoemaker et al, 2008). Gonadoblastoma is associated with dysgerminoma or other germ cell neoplasms in 18% to 35% of cases, sometimes associated with virilization (Cools et al, 2011; Zelaya et al., 2015). **Because the age of occurrence of gonadoblastoma is variable and has been reported as early as 5 months of age, timely prophylactic excision of the streak gonads in the Y mosaic Turner syndrome patient is advised** (Coyle et al., 2016). This may be well performed laparoscopically. Streak gonads confirmed to be in 45,XO patients need not be removed. In a British national cohort study, there was also an increased risk for bladder and urethral cancer in Turner syndrome patients followed into adulthood (Schoemaker et al., 2008).

Between 33% and 60% of patients with Turner syndrome have structural or positional abnormalities of the kidney; this occurs most frequently in the classic 45,XO karyotype (Hall and Gilchrist, 1990). **Horseshoe kidney accounts for 10%, duplication or renal agenesis for 20%, and malrotation for 15% of these abnormalities.** Multiple renal arteries have been noted in 90% of patients with Turner syndrome as a result of their cardiovascular evaluation (Hall and

Gilchrist, 1990).

The contemporary treatment of patients with Turner syndrome has undergone considerable advances. In the neonate, it entails a concerted search for occult Y chromosomal material, including fluorescent in-situ hybridization (FISH) or PCR and, subsequently, prophylactic gonadectomy if necessary and ultrasound screening for renal and cardiac abnormalities such as bicuspid aortic valves (Klásková et al., 2017). **In the child, human growth hormone has successfully been employed** to achieve increased adult height (Pasquino, 2004). At an appropriate age, typically between 12 and 15 years, exogenous hormonal therapy to induce puberty and then to maintain a normal female endocrine status is begun. An improved understanding of the long-term medical management of these patients, including cardiac surveillance and management of glucose intolerance, autoimmune disorders, and osteoporosis, has also resulted in considerable progress. **Finally, with the remarkable advances in assisted reproductive technology, pregnancy is a realistic possibility for patients with Turner syndrome, although spontaneous fertility is rare** (Sybert and McCauley, 2004). A spectrum of potential gonadal function has been noted in large series of patients with Turner syndrome (Kaneko et al., 1990). In one series, nonstreak gonads were reported in one-third of such patients and were more commonly noted in girls with loss of only the short arm of the X chromosome. In 2% to 5% of Turner syndrome patients, spontaneous menses will occur with a potential to achieve pregnancy independently (Saenger et al., 2001). This appears most likely in women with mosaicism for a normal 46,XX cell line, a 47,XXX cell line, or distal Xp deletion. To date, more than 160 pregnancies have been reported among spontaneously menstruating Turner syndrome patients. For the vast majority with true streak gonads, for whom egg donor implantation is used, 40% to 50% pregnancy rates have been reported by centers specializing in in-vitro fertilization (Saenger, 1993). However, among these rare pregnancies, the rates of miscarriage, stillbirth, and malformed infants is high (Abir et al., 2001). Because there is a high likelihood of premature ovarian failure, early oocyte preservation may be useful for long-term fertility preservation. Techniques for mature oocyte cryopreservation have dramatically improved, resulting in guidelines stating that the technology should no longer be considered experimental (Practice Committees of the American Society for Reproductive Medicine and the Society for Assisted Reproductive Technology, 2013). However, the risk for chromosomal abnormalities and unknown efficacy of oocyte preservation in this population require further investigation.

It is of great interest that neuroanatomic imaging studies of 45,XO Turner syndrome patients have demonstrated differences in parietal and temporal lobe anatomy and posterior fossa morphology that appear to correlate with certain established neurophysiologic and cognitive deficits (Brown et al, 2004; Rae et al, 2004).

Psychosocial care of the Turner syndrome patient throughout childhood and transition to adult care, including disclosure, has been increasingly emphasized (Amedro et al., 2017; Culen et al., 2017).

Key Point: Turner Syndrome

- In patients with Turner syndrome and occult Y chromosomal material, the risk for gonadoblastoma, an in-situ germ cell cancer, is 12% and is being further defined.
- Young women with Turner syndrome and spontaneous menses are at high risk for premature ovarian failure. However, mature oocyte cryopreservation is currently considered experimental.

46,XX “Pure” Gonadal Dysgenesis.

Patients with 46,XX “pure” gonadal dysgenesis are characterized by normal female external genitalia, normal müllerian ducts with absence of wolffian duct structures, a normal height, bilateral streak gonads, sexual infantilism, and a normal 46,XX karyotype. The streak gonads result in elevated serum gonadotropins. Because these subjects exhibit none of the somatic stigmata associated with Turner syndrome, and their condition entails gonadal dysgenesis only, it has been regarded by some authors as “pure.”

A familial incidence of 46,XX gonadal dysgenesis has been reported as an autosomal recessive trait (Espiner et al., 1970). This suggests the possibility that autosomal genes in addition to genes on the X chromosome may be involved in ovarian maintenance.

Management of patients with 46,XX “pure” gonadal dysgenesis entails proper cyclic hormone replacement with estrogen and progesterone. In contrast with Turner syndrome, growth is not abnormal with this condition, and therefore growth hormone should not be required. Because, by definition, these patients have no Y chromosomal material, gonadectomy is not required.

Mixed Gonadal Dysgenesis.

The term *mixed gonadal dysgenesis* was coined by Sohval in 1963 (Sohval, 1963). In 1975, Zah et al. reported on their series of more than 100 patients with 45,X/46,XY karyotypes, 72 of whom had mixed gonadal dysgenesis with a streak gonad on one side and a testis on the other (Zah et al., 1975).

Mixed gonadal dysgenesis is characterized by a unilateral testis, which is often intra-abdominal, a contralateral streak gonad, and persistent müllerian structures associated with varying degrees of inadequate masculinization. Most patients with mixed gonadal dysgenesis have a 45,XO/46,XY karyotype, which is probably the result of anaphase lag during mitosis. The 45,X/46,XY mosaicism is the most common form of mosaicism involving the Y chromosome.

The phenotypic spectrum of patients with XO/XY mosaicism ranges from phenotypic females with Turner syndrome, to those with ambiguous genitalia, to those with normal male genitalia (Johansen, 2012). **In the neonatal period, mixed gonadal dysgenesis is the second most common cause of ambiguous genitalia (after CAH) and must be in the differential diagnosis.** The majority of these patients present with varying degrees of phallic development, a urogenital sinus with labioscrotal fusion, and an undescended testis. In virtually all of these patients, a uterus, vagina, and fallopian tube are present. Short stature and associated somatic stigmata are variable features.

Key Point: Mixed Gonadal Dysgenesis

- In the newborn period, mixed gonadal dysgenesis is the second most common cause of ambiguous genitalia (after CAH) and must be in the differential diagnosis.

The phenotypic asymmetry of the internal ducts epitomizes the mechanism of local testosterone and AMH production on müllerian and wolffian duct regression and development. In the series of Mendez et al. (1993) comprising 16 patients, all had a fallopian tube accompanied by a streak gonad, consistent with absent AMH. **Therefore, whereas a dysgenetic or streak gonad is associated with ipsilateral müllerian derivatives (uterus, fallopian tube)** (Fig. 48.16), **a well-differentiated testis with functional Sertoli and Leydig cells will have ipsilateral wolffian but no müllerian ducts** (Davidoff and Federman, 1973). In addition, the presence of severe external genital ambiguity in many of these patients suggests that testosterone production in utero was inadequate to promote complete differentiation of the external genitalia. Yet, despite postpubertal endocrine function, it is postulated that fetal testicular endocrine function is either delayed or deficient. Martinerie et al. found that 55% of 45X/46XY males required testosterone therapy to complete puberty, and no patient was fertile (Martinerie et al., 2012). Histologically, the testes lacked germinal elements, so infertility was anticipated. However, successful sperm extraction has been reported.

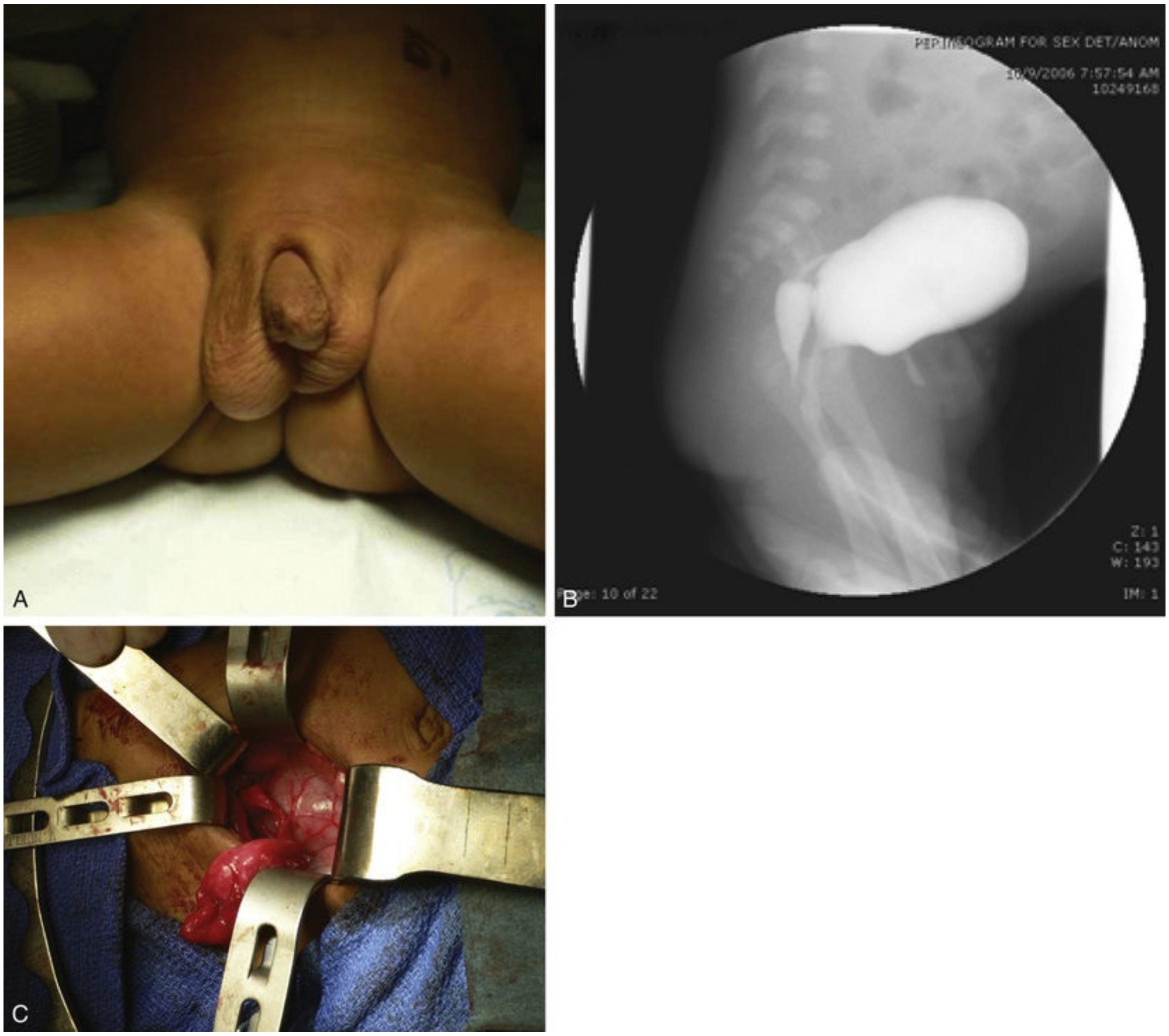

FIG. 48.16 (A) Patient with mixed gonadal dysgenesis showing asymmetrical anatomy. (B) Hemiuterus and opacified fallopian tube in left inguinal hernia. (C) Structures noted in (B) shown at surgical exploration.

The risk for developing a gonadal tumor (gonadoblastoma, dysgerminoma) is increased in mixed gonadal dysgenesis, with an estimated incidence of 15% to 35% (Robboy et al., 1982; Wallace and Levin, 1990). Gonadoblastoma, a premalignant lesion, is the most common. It was so named because it recapitulates gonadal development more completely than any other tumor (Scully, 1970). **Germ cell tumors occur both in the streak gonads and in the dysgenetic testes of individuals with 46,X/46,XY mosaicism. Cools et al. noted the greatest risk for tumor or preneoplastic lesion with streak gonads and when the phenotype was ambiguous (52%), and less risk with mild undervirilization and scrotal testes (13%)** (Cools et al, 2011).

Patients with mixed gonadal dysgenesis are also at increased risk for Wilms tumor. Rajfer (1981) reported that 50% of 10 patients with a DSD and Wilms tumor had mixed gonadal dysgenesis. He postulated that there was a genetic or teratogenic defect involving the urogenital ridge, the common embryonic anlage of both kidney and gonad. This concept was borne out by improved understanding of the Denys-Drash syndrome, now clearly associated with mutations in the Wilms tumor suppressor gene *(WT1)*. In 1967, Denys et al. described a child with XX/XY mosaicism, nephropathy, genital abnormalities, and Wilms tumor. Drash et al. (1970) reported two further examples in 1970. **The full triad of the syndrome includes nephropathy, characterized by early onset of proteinuria and hypertension, and progressive renal failure in most patients.** Renal histology demonstrates diffuse focal mesangial sclerosis. **Because incomplete forms of the syndrome may occur, the nephropathy has become regarded as the common denominator of the syndrome** (Habib et al., 1985). Wilms tumor may be diagnosed before, after, or simultaneously with presentation with nephropathy. The majority of the tumors are of favorable triphasic histology (Beckwith and Palmer, 1978). However, there is a high incidence of bilateral Wilms tumor in this syndrome. The genital abnormalities include frank ambiguity, hypospadias, and cryptorchidism. **A large number of patients with Denys-Drash syndrome have been noted to have mixed gonadal dysgenesis.** These have an increased risk for gonadal tumor of 40% (Table 48.3) (Lee et al., 2006). An interesting and relatively consistent finding with Denys-Drash syndrome is that of caliceal blunting without obstruction (Jadresic et al., 1990). The high mortality rate associated with this syndrome has prompted an aggressive treatment approach with prophylactic bilateral nephrectomy in an attempt to improve the prognosis for these children (Jadresic et al., 1990).

TABLE 48.3

Risk for Germ Cell Malignancy According to Diagnosis

RISK GROUP	DISORDER	MALIGNANCY RISK (%)
High	GD[a] (+Y)[b] intra-abdominal	15–35
	PAIS nonscrotal	50
	Frasier	60
	Denys-Drash (+Y)	40
Intermediate	Turner (+Y)	12
	17β-hydroxysteroid	28
	GD (+Y)[b] scrotal	Unknown
	PAIS scrotal gonad	Unknown
Low	CAIS	2
	Ovotesticular DSD	3
	Turner (–Y)	1

[a] Gonadal dysgenesis (including not further specified, 46,XY, 46,X/46,XY, mixed, partial, and complete).

[b] GBY region positive, including the *TSPY* (testis-specific protein Y encoded) gene.

CAIS, Complete androgen insensitivity syndrome; *PAIS,* partial androgen insensitivity syndrome.

Data from Lee PA, Houk CP, Ahmed F, et al. Consensus statement on management of intersex disorders. *Pediatrics*. 2006;118:e488–e500.

Frasier syndrome, a related disorder caused by mutations in the alternative splice donor site of exon 9 on *WT1*, presents in similar fashion to Denys-Drash syndrome but with certain important distinctions (Klamt et al., 1998). The nephropathy caused by focal segmental glomerulosclerosis occurs later in life with a more gradual progression to renal failure (Koziell et al., 1999). There is no known predisposition to Wilms tumor. Gonadoblastomas in 46,XY individuals are far more common in Frasier syndrome than in Denys-Drash syndrome with a gonadal tumor risk for 60% (see Table 48.3). These individuals typically have a female phenotype, but rarely male phenotypes will occur (Ezaki et al., 2015). Because 46,XX individuals with Frasier syndrome have normal gonadal development, they would present with renal failure. But, it is presumed that many such 46,XX individualso go undiagnosed. Frasier syndrome should be considered for girls presenting with steroid-resistant nephrotic syndrome, primary amenorrhea, and pubertal delay (Gwin et al., 2008).

The management of mixed gonadal dysgenesis entails gender assignment, appropriate gonadectomy, and proper screening for Wilms tumor. If the diagnosis is made in the neonatal period, the decision regarding sex of rearing should be based on the potential for normal function of the external genitalia and gonads. Historically, two-thirds of patients with mixed gonadal dysgenesis have been raised as female. Potential fertility is not a significant issue in this disorder, and therefore the anatomy of the reproductive tract may direct the decision making. The likelihood of significant androgen imprinting is greater in association with a better-masculinized phenotype, and this may serve as the best clinical guide. For patients with Turner syndrome stigmata and growth below the fifth percentile, growth hormone therapy may be appropriate. If the male gender is elected and the testis can be brought to the scrotum, the decision between careful screening for gonadoblastoma (with physical examination and ultrasonography) versus prophylactic gonadectomy and androgen replacement must be made. Gonadal biopsy with immunohistochemistry after 1 year of age or postpubertally may be instructive (Cools et al., 2011).

The expanded use of prenatal diagnosis has changed the understanding of 45,X/46,XY mosaicism. Studies have shown that 90% to 95% of all infants with 45,X/46,XY mosaicism have normal-appearing male genitalia (Hsu, 1989). Approximately 25% have abnormal gonadal histology (Chang et al., 1990). Because only a small proportion of those with dysgenetic gonads actually have ambiguous genitalia, the possibility exists that some males with gonadal dysfunction and infertility have 45,X/46,XY mosaicism.

Partial Gonadal Dysgenesis.

In 1967, Federman coined the term *dysgenetic male pseudohermaphroditism,* **which is a condition closely related to mixed gonadal dysgenesis in that patients with abnormal sexual development have two dysgenetic testes rather than one dysgenetic testis and a streak gonad** (Federman, 1967). Others have applied the term *partial gonadal dysgenesis* to this condition to distinguish it from mixed and complete forms of gonadal dysgenesis. As with mixed gonadal dysgenesis, these individuals typically have a 45,X/46,XY or 46,XY karyotype. They may present with a spectrum of external genital abnormalities, depending on the capability of the dysgenetic gonads to produce testosterone. Similarly, persistent müllerian structures are typically present, but to varying degrees depending on AMH secretion by the dysgenetic gonads.

Fabbri et al. noted that *NR5A1* loss-of-function mutations account for 15% of cases of partial gonadal dysgenesis (Fabbri et al., 2016). On histology, the dysgenetic testis is found to be composed of immature hypoplastic seminiferous tubules and persistent stroma resembling that seen in the streak gonad.

Patients with partial gonadal dysgenesis are at increased risk for gonadal malignancy. Manuel et al. (1976) reported that the incidence of gonadoblastoma or dysgerminoma was 46% by 40 years of age. These patients are also at risk for Denys-Drash syndrome (Borer et al., 1995).

The management of partial gonadal dysgenesis, in terms of gender assignment and surveillance for malignancy, is similar to that for patients with mixed gonadal dysgenesis.

46,XY Complete (Pure) Gonadal Dysgenesis (Swyer Syndrome).

Just as 46,XX males were of great importance in discovery of the TDF, so too have been the 46,XY females. **Patients with 46,XY complete gonadal dysgenesis are characterized by normal female genitalia, well-developed müllerian structures, bilateral streak gonads, and a nonmosaic karyotype.** Because there is complete absence of testicular determination in this condition, ambiguity of genitalia is not an issue, but sexual infantilism is the primary clinical problem.

The etiology of 46,XY complete gonadal dysgenesis may well be an abnormality of the *SRY* gene that eliminates SRY function or loss of another gene downstream from *SRY* that is necessary for SRY protein action. In either case, the absence of testicular determination would permit ovarian differentiation. To date, mutations in the *SRY* gene are the cause of 46,XY complete gonadal dysgenesis in 10% to 15% of cases (Bastian et al., 2015). Bastian et al. identified mutation in 50% of patients with 46,XY gonadal dysgenesis, including *SRY*, *WT1,* and *Fog 2/ZFPM2* and deletion of distal chromosome 9P. Mutation in the Desert hedgehog *(DHH)* gene was noted in 3 of 6 patients with 46,XY complete gonadal dysgenesis, suggesting that the genetic origin of this entity is heterogeneous and *DHH* is likely an important gene in gonadal differentiation (Canto et al., 2004). Novel *NR5A1* mutations have recently been associated with 46,XY gonadal dysgenesis (Rehkämper et al., 2017).

The majority of individuals with 46,XY complete gonadal dysgenesis present in their teens with delayed puberty and amenorrhea. Breast development is usually absent. The serum concentration of gonadotropins is abnormally elevated, which leads the clinician to the determination of karyotype and the subsequent diagnosis (Grumbach and Conte, 1998). The high concentration of serum LH in these patients is thought to be responsible for the increased androgen levels that lead to clitoromegaly in some individuals (Fig. 48.17).

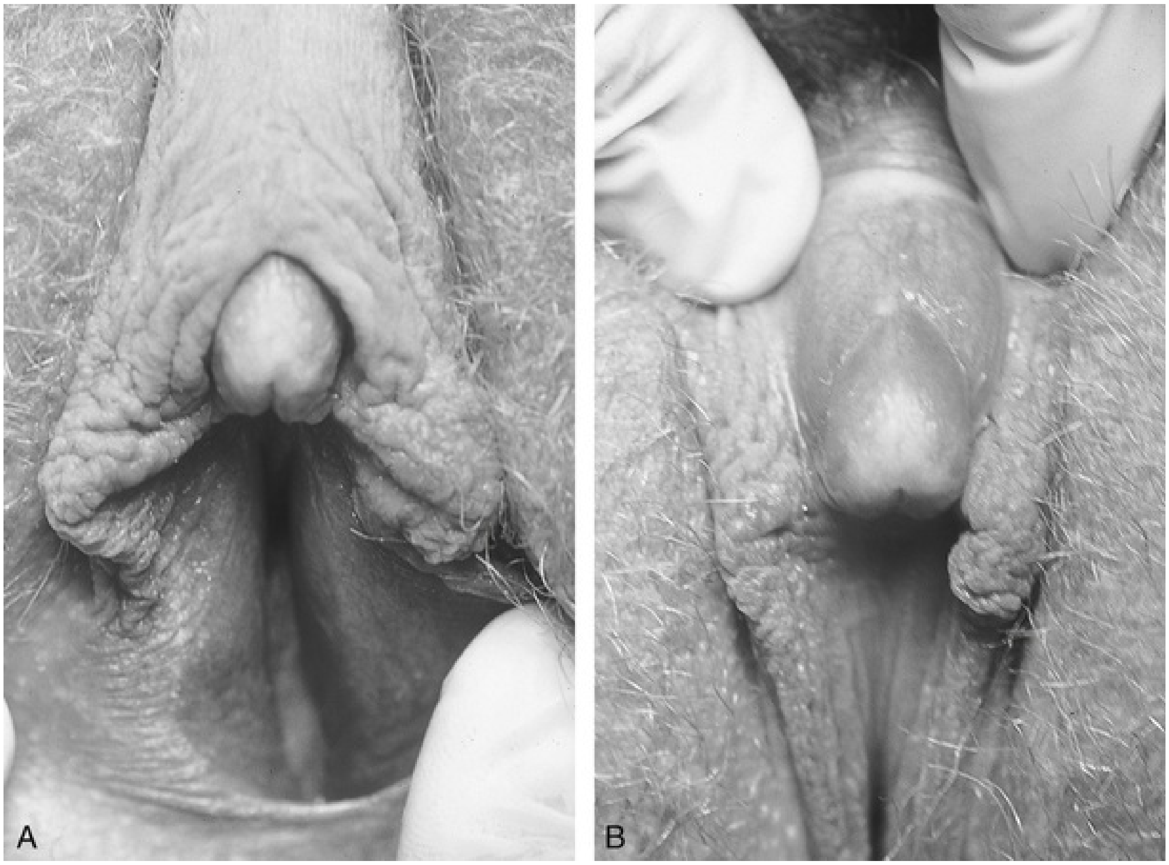

FIG. 48.17 (A and B) External genitalia of a 15-year-old female presenting with amenorrhea and hirsutism who was diagnosed with 46,XY gonadal dysgenesis, demonstrating clitoromegaly and urogenital sinus. (Courtesy of S. Bauer, MD.)

The histology of the streak gonad is similar to that of Turner syndrome, with fibrous connective tissue resembling wavy ovarian stroma but without follicles. Some histologic variability has been noted, with more proliferative-appearing stroma in some and, rarely, preservation of intact primordial follicles. This variability in ovarian histology is thought to support the hypothesis that these gonads developed as ovaries in utero (German et al., 1978). This would resemble the process that occurs in the streak gonad of Turner syndrome.

Patients with 46,XY complete or pure gonadal dysgenesis are at significant risk for germ cell tumors. There appears to be up to a 35% risk for tumor development by 30 years of age (Manuel et al, 1976**; see Table**

48.3). Gonadoblastoma is most common, and it is frequently bilateral (Fig. 48.18). Other tumors that may arise in this patient population include embryonal carcinoma, endodermal sinus tumor, choriocarcinoma, and immature teratoma. These more highly malignant tumors occur in fewer than 10% of patients with 46,XY complete gonadal dysgenesis (Scully, 1981).

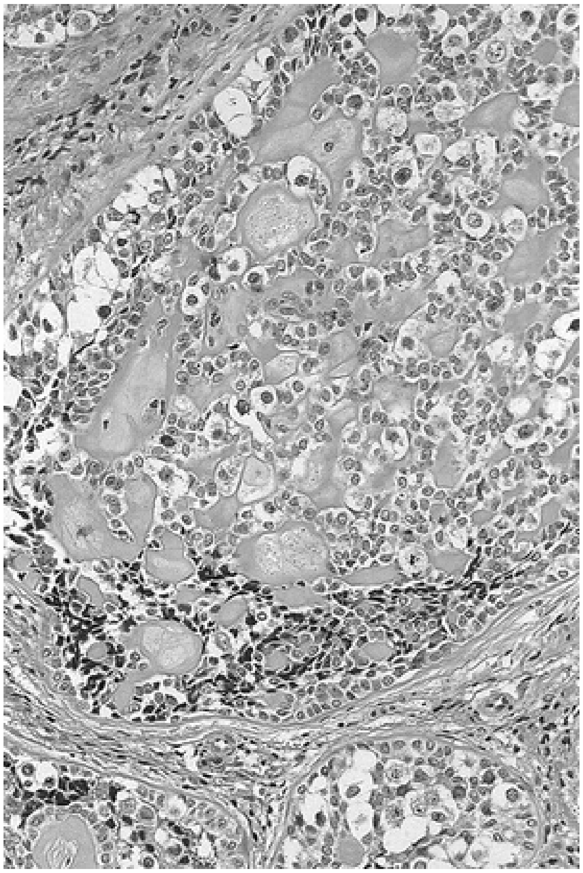

FIG. 48.18 Pathology of gonadoblastoma discovered in the patient shown in Fig. 48.17 with 46,XY gonadal dysgenesis. Encapsulated nests of gonadoblastoma comprise small sex cord–type cells arranged around rounded spaces of amorphous eosinophilic material and interspersed germ cells. (Courtesy of S. Bauer, MD.)

Management of 46,XY complete gonadal dysgenesis entails removal of both streak gonads and proper cyclic hormone replacement with estrogen and progesterone.

Embryonic Testicular Regression and Bilateral Vanishing Testes Syndromes

The syndromes of embryonic testicular regression and bilateral vanishing testes are characterized by **patients with a 46,XY karyotype and absent testes in whom there is clear evidence of testicular function at some point during embryogenesis.** The syndrome entails the presence of testes that "vanish" during embryogenesis and is distinguished from pure gonadal dysgenesis, in which there is no evidence of testicular function in utero.

These syndromes have been regarded as synonymous by some authors. Other authors, including Migeon et al. (1994), have suggested a rational stratification whereby "embryonic testicular regression" refers to loss of testicular tissue within the first trimester and is associated with ambiguity of external genitalia, whereas "bilateral vanishing testes syndrome" refers to individuals in whom male sexual differentiation of ducts and genitalia took place but loss of testicular tissue occurred subsequently in utero.

The etiology of these disorders remains unclear. **It is possible that regression of the testes in utero is caused by a genetic mutation, a teratogen, or bilateral torsion.** A genetic cause is supported by the finding of familial instances of XY agonadism that might be consistent with the rare recessive trait. Marcantonio et al. (1994) suggested the possibility that embryonic testicular regression represents a variant of 46,XY gonadal dysgenesis. They noted a group of patients with absent testes but evidence of incongruity between the extent of Leydig cell and Sertoli cell function, suggesting that gonadal tissue in these subjects was intrinsically abnormal before the testicular regression occurred. The occurrence of embryonic testicular regression in several subjects from one family in their series suggested a genetic basis for the condition, and the pattern of inheritance implicated the involvement of an X-chromosome gene. In another group of patients, these authors noted multiple congenital anomalies, suggesting either a mutation in a single gene that functions in several developmental pathways or a defect of multiple genes that might be the result of a large chromosomal deletion. A heterozygous mutation in *NR5A1* has been noted in a series of patients with bilateral vanishing testes syndrome with micropenis (Philibert et al., 2007).

Clinically, these two syndromes represent a spectrum of phenotypes ranging in severity from complete female, to varying degrees of genital ambiguity in the embryonic testicular regression syndrome, to a normal male phenotype with microphallus and empty scrotum in the bilateral vanishing testes syndrome (Edman et al, 1977). **The diagnosis can be made on the basis of a 46,XY karyotype, castrate levels of testosterone, elevated serum LH and FSH**

during “mini-puberty” from 2 to 6 months of age (Jarow et al, 1986), and undetectable AMH level (Lee et al, 2003). In the most severe form of embryonic testicular regression syndrome, agonadism is discovered in a 46,XY phenotypic female with no internal genital structures. This picture is presumed to result when the testis has elaborated AMH but vanishes at approximately day 60 to 70 of gestation, before the elaboration of androgen. Because of the absence of gonadal androgens later in fetal development and transient expression of AMH, the individual goes on to develop a sexually infantile female phenotype but lacks any internal ductal structures. At an intermediate point in the clinical spectrum is the 46,XY patient with absent gonads and internal ductal structures but with ambiguous genitalia owing to incomplete elaboration of androgen by the vanishing testes. Finally, in bilateral vanishing testes syndrome, patients may present as agonadal XY phenotypic males with fully developed wolffian structures but an empty scrotum, absent prostate, and microphallus. This represents testicular loss after complete anatomic development of the male external genitalia within the first trimester.

On surgical exploration of patients with bilateral vanishing testes syndrome, rudimentary cord structures are usually identified, and biopsy of their distal ends demonstrates no recognizable testicular tissue histologically, only hemosiderin deposits (Bergada et al., 1962). Atrophic epididymal remnants are occasionally seen.

The management of patients with embryonic testicular regression syndrome or bilateral vanishing testes syndrome is dictated by their position in the clinical spectrum of either disorder. Sexually infantile phenotypic females require estrogen supplementation at the time of expected puberty for development of secondary sexual characteristics and may require vaginal dilation or vaginoplasty. Similarly, phenotypic males require long-term androgen replacement beginning at the time of expected puberty. A study of 21 males so treated demonstrated that replacement therapy started at the correct time caused a normal pubertal growth spurt with normal secondary sex characteristics including penile growth, together with normal bone maturation (Aynsley-Green et al., 1976). In addition, these patients may benefit from placement of testicular prostheses, although optimal timing remains controversial. Patients with embryonic testicular regression syndrome and ambiguous genitalia require individualized assessment to determine the optimal gender assignment.

Ovotesticular DSD

Ovotesticular DSD describes individuals who have both testicular tissue with well-developed seminiferous tubules and ovarian tissue with primordial follicles, which may take the form of one ovary and one testis or, more commonly, one or two ovotestes.

Both the external genitalia and internal duct structures of ovotesticular DSD display gradations between male and female. **In most patients the external genitalia are ambiguous but masculinized to varying degrees, and 75% are raised as male.** Among those raised as male, hypospadias and chordee occur in approximately 80%. Among those patients raised as females, two-thirds have clitoromegaly. Virtually all patients have a urogenital sinus, and in most cases a uterus is present (see Figs. 48.16 and 48.17). The ovary is found in a normal location, more commonly on the left side. The testis or ovotestis may reside at any point along the path of testicular descent. Testes and ovotestes are more commonly located on the right side (Blyth and Duckett, 1991; Mittwoch, 2000). Sixty percent of gonads palpable in the inguinal canal or labioscrotal folds are ovotestes, which may be clinically suspected on the basis of a difference in firmness at either end of the gonad, consistent with polar segregation of ovarian and testicular tissue (Grumbach and Conte, 1998). A recent review of a large cohort of patients with ovotesticular DSD from South Africa demonstrated 56% of gonads to be ovotestes, 23% to be ovaries (more commonly left-sided), and 16% to be testes (typically right-sided) (Ganie et al., 2017). Detailed evaluation of gonads from this large cohort of patients suggests three distinct patterns of gonad development admixed (central core containing stroma and a mixture of ovarian and testicular tissue), compartmentalized (ovarian tissue in upper pole with lower pole of testicular tissue encapsulated by mantle of ovarian tissue), and bipolar (strict polar distribution of testicular and ovarian tissue) (Wiersma and Ramdial, 2009).

Approximately 60% of ovotesticular DSDs have a 46,XX karyotype; 33% are mosaics with a second cell line containing a Y chromosome (46,XX/46,XY; 46,XX/46,XXY), and 7% are 46,XY. Chimerism (mosaicism) has been thought to result from fusion of a fertilized ovum with its polar body, fusion of two nuclei, or double fertilization. It has also been suggested that ovotesticular DSD may result from hidden mosaicism with a Y cell line. Ortenberg et al. (2002) demonstrated the *SRY* gene in ovotestes of all eight cases of ovotesticular DSD studied, supporting somatic mosaicism. Other studies have demonstrated heterogeneity of Y-specific DNA regions detected in patients with ovotesticular DSD (Hadjiathanasiou et al., 1994). This supports a non–Y-chromosome–related mechanism responsible for 46,XX ovotesticular DSD, such as mutation in an autosomal or X-linked gene involved in sex determination. Recently, Bashamboo et al. and Baetens et al. noted a mutation in *NR5A1* to be responsible for ovotesticular DSD by disinhibition of the male developmental pathway, through down-regulation of female antitestis genes, tipping the balance toward testicular differentiation in 46,XX individuals (Bashamboo et al., 2016; Baetens et al., 2017). **Just as the differentiation of external genitalia is variable in ovotesticular DSD, differentiation of the internal ducts is also quite variable and is related to the function of the ipsilateral gonad.** Fallopian tubes are consistently present on the side of the ovary, and a vas deferens is always present adjacent to a testis (Berkovitz et al., 1991). The ovotestis, which comprises two-thirds of gonads in ovotesticular DSD, is associated with a fallopian tube in two-thirds of cases and with either a vas deferens only or both structures in one-third of cases.

The ovarian portion of the ovotestis is frequently normal, whereas the testicular portion is typically dysgenetic. Therefore, although ovulation and pregnancy have been reported for female 46,XX ovotesticular DSDs, male fertility has not been clearly documented.

The incidence of gonadal tumors is approximately 3% in 46,XY ovotesticular DSD and rare in 46,XX ovotesticular DSD. Both gonadoblastoma and dysgerminoma have been described (Verp and Simpson, 1987).

The most important aspect of management in ovotesticular DSD is gender assignment. Sex assignment should be based on the functional potential of external genitalia, internal ducts, and gonads according to the findings at laparoscopy or laparotomy. **Unlike patients with most other forms of gonadal dysgenesis, individuals with ovotesticular DSD have the potential for fertility if raised as female with the appropriate ductal structures.** Pregnancies have been reported in patients with ovotesticular DSD, the majority with the 46,XX karyotype (Starceski et al., 1988). If the patient is to be raised as female, all testicular and wolffian tissue should be removed. For those patients with an ovary, this is straightforward; if an ovotestis is present, surgical cleavage of the gonad with excision of the testicular portion has been performed successfully by Nihoul-Fekete et al. (1984). They recommend postoperative stimulation with human chorionic gonadotropin (hCG) to confirm that all testicular tissue has been removed. In settings in which the cleavage plane between testicular and ovarian tissues is unclear, as in admixed pathology described earlier, gonadectomy is advisable. When ovarian tissue is preserved, normal ovarian function can occur at puberty, although hormonal replacement may be necessary. Careful surveillance for potential gonadal tumors in the patient raised as female is also advisable. If a male gender is assigned, as has been most common historically, all ovarian and müllerian tissue should be removed. Consideration should be given to gonadectomy at puberty with appropriate androgen replacement in this setting, given the high risk for malignancy and unlikelihood of male fertility. At the very least, long-term gonadal surveillance ultrasound for tumor development would seem appropriate.

46,XX DSD (Masculinized Female)

46,XX DSD (masculinized female) is a disorder of phenotypic sexual development in which 46,XX individuals with ovaries have partially masculinized phenotype and ambiguous genitalia. By far the most common cause of the masculinized female is congenital adrenal hyperplasia (CAH), which is the most common cause of ambiguous genitalia in the newborn. Two very rare causes of 46,XX DSD (masculinized female) are maternal ingestion of androgens and virilizing tumors in the mother.

Congenital Adrenal Hyperplasia

The adrenogenital syndrome caused by CAH is a classic example of an inborn error of metabolism—in this case, an error involving cortisol synthesis. A defect in any one of the five enzymes involved in the cortisol biosynthetic pathway (cholesterol side-chain cleavage enzyme, 3β-hydroxysteroid dehydrogenase, 17-hydroxylase, 21-hydroxylase, and 11-hydroxylase) may result in CAH. The most commonly recognized syndromes result from a deficiency of one of the terminal two enzymes of glucocorticoid synthesis (21-hydroxylase or 11-hydroxylase) (New and Levine, 1984) (Fig. 48.19). As a result of deficiency of either terminal enzyme, formation of hydrocortisone is impaired, causing a compensatory increase in the secretion of adrenocorticotrophic hormone (ACTH). This increase enhances formation of adrenal steroids proximal to the enzymatic defect and a secondary increase in the formation of testosterone, the active androgen in CAH.

Key Point: Congenital Adrenal Hyperplasia

- The most commonly recognized syndromes of CAH result from a deficiency of one of the terminal two enzymes of glucocorticoid synthesis (21-hydroxylase or 11-hydroxylase).

A deficiency of steroid 21-hydroxylase is responsible for 95% of cases of CAH; it occurs with an incidence ranging from 1 in 5000 to 1 in 15,000 in the United States and Europe. The highest incidence, 1 in 490, is reported in the Yupik Alaskan Eskimo population (New et al., 1994). **Clinically, patients are divided into three categories: (1) salt wasters (patients with virilization and aldosterone deficiency), (2) simple virilizers (patients with virilization but without salt wasting), and (3) nonclassic patients (those without evidence of virilization or salt wasting).** Dramatic progress has been made in understanding the molecular basis of CAH, and 95% of the mutations that account for CAH have been identified. The wide clinical spectrum of the disease appears to represent different degrees of enzymatic compromise conferred by specific, identifiable genetic defects.

The 21-hydroxylase gene *(CYP21A2)* is located on chromosome 6p21.3 within the major human leukocyte antigen (HLA) complex and is transmitted in an autosomal recessive pattern (Wilson et al, 1995). Adjacent to the *CYP21A2* gene, separated by 30 kb, and adjacent to and alternating with *C4B* and *C4A* genes encoding the fourth component of serum complement is the CYP21 pseudogene *(CYP21PA1)*, so called because it encodes no proteins and is therefore inactive (Tusie-Luna and White, 1995). The inactive *CYP21PA1* is 98% homologous to the active gene *CYP21A2*. During meiosis, a gene conversion may occur that transfers segments from the *CYP21PA1* gene to the *CYP21A2* gene, rendering it inactive. Thus far, all mutations causing 21-hydroxylase deficiency appear to result from either a complete deletion of the genes *C4B* and *CYP21B* (a product of misalignment and unequal crossing over between chromatids during meiosis). To date, approximately 10 mutations constitute 90% to 95% of alleles and are derived from intergenic recombination of DNA sequences between the *CYP21A2* gene and the highly homologous *CYP21PA1*, whereas the remaining are spontaneous mutations (Forest, 2004). Over 200 different *CYP21* mutations have been reported (Witchel et al., 2017).

The majority of patients with CAH secondary to 21-hydroxylase deficiency exhibit one of the two classic forms of the disease: **75% present with salt wasting and 25% with simple virilization** (Kohn et al., 1995). The higher proportion of patients with the salt-wasting form of the disease recognized in more recent series has been attributed to improved diagnostic capabilities and a high level of clinical suspicion as well as to increased survival resulting from prenatal screening and proper mineralocorticoid supplementation (Fife and Rappaport, 1983). Neonatal screening programs for CAH, utilized in all 50 states and over 40 countries, have been credited with increasing the rate and shortening the time to diagnosis, particularly in males with the salt-wasting form of the disease (El-Maouche et al, 2017). This has also proven to be an important means of diagnosing the simple virilizing form in the male and the nonclassic forms in some males and females (Brosnan et al., 1999).

In the female with the classic salt-wasting and simple virilizing forms of the disorder, a masculinized female results. Because impaired steroidogenesis begins early in life—at the time of formation of the external genitalia (beginning at 10 weeks' gestation)—there is virtually always evidence of some degree of masculinization at birth. This is manifested by enlargement of the clitoris and varying degrees of labial fusion (Fig. 48.20). In addition, the vagina and urethra open into a common urogenital sinus. The enlargement of the clitoris may be so dramatic as to make it appear to be a hypospadiac penis with bilateral cryptorchidism or, rarely, a fully masculinized urethra to the tip of an apparent glans penis (Fig. 48.21). The severity of the virilization is usually greater in infants who experience salt wasting but not uniformly so. Prader (1958) classified the degrees of virilization of external genitalia in females with CAH (Fig. 48.22). The müllerian structures in these patients are typically normal. There may be an increased incidence of upper tract abnormalities (hydronephrosis, duplication) in CAH (Nabhan and Eugster, 2007).

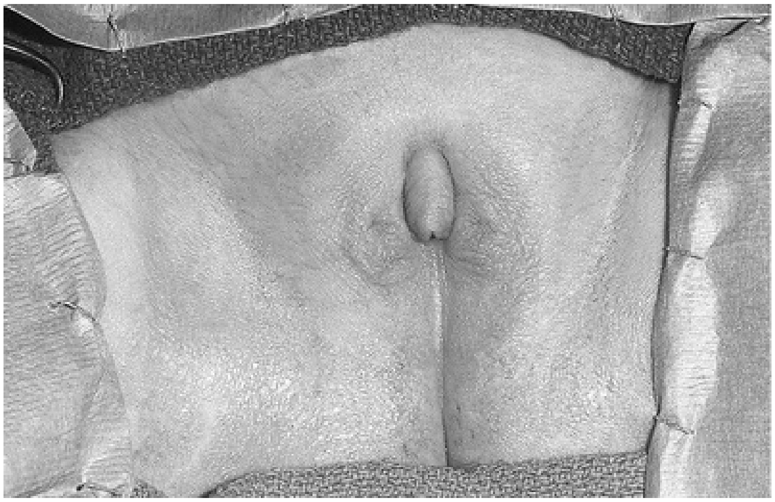

FIG. 48.20 External genitalia of a patient with congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency, showing labioscrotal fusion and clitoromegaly.

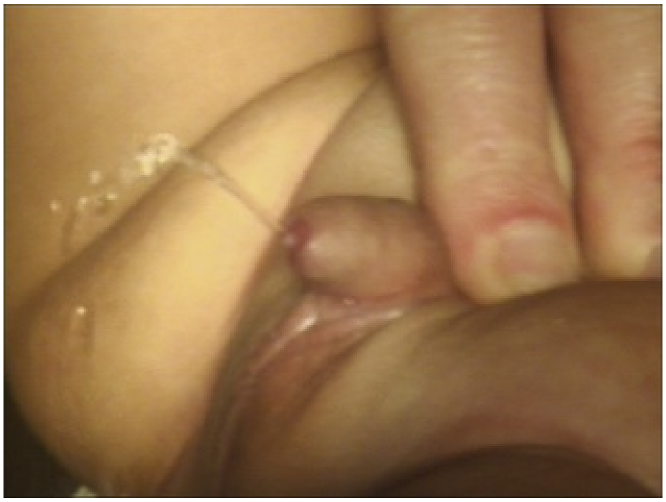

FIG. 48.21 Prader V patient with congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency demonstrating complete virilization of phallus.

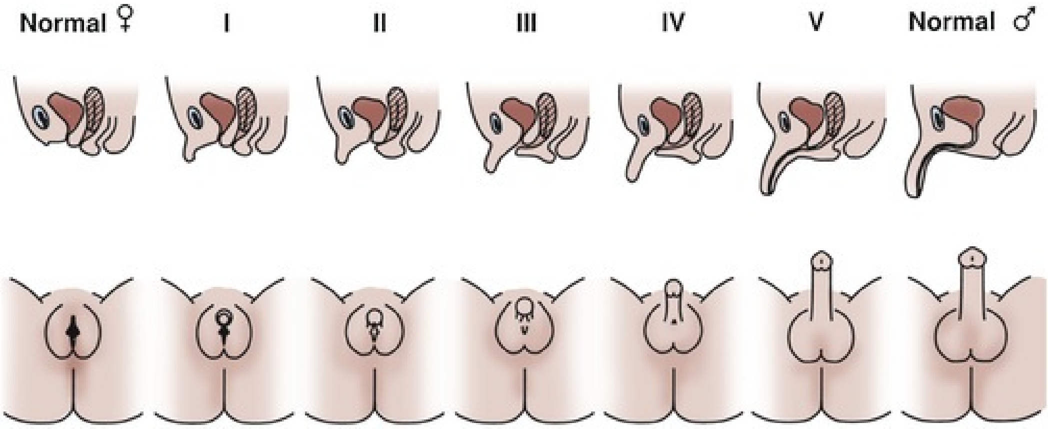

FIG. 48.22 Classification by Prader of the various degrees of masculinization of the external genitalia in females with congenital adrenal hyperplasia that has been applied by some authors to intersexual states in general. (From Prader A. Die Haufigkeit der kongenitalen androgenitalen Syndroms. *Helv Pediatr Acta.* 1958;13:426.)

In both males and females with the salt-losing variant of CAH, symptoms begin within the first few weeks after birth, with failure to regain birth weight, progressive weight loss, and dehydration. In severely affected infants, adrenal crises occur within the first 10 to 21 days of life (Grumbach and Conte, 1998)**. Vomiting is prominent and can be so extreme that a mistaken diagnosis of pyloric stenosis is made, particularly in the male.** Without therapy, death may rapidly ensue from hyperkalemia, dehydration, and shock. In the male infant, in particular, the classic fluid and electrolyte abnormalities of CAH may be mimicked by urosepsis secondary to reflux or obstructive uropathy, which should be ruled out (Mastrandrea et al., 2005). After birth, there is progression of masculinization of the untreated female; pubic and axillary hair develop prematurely, acne appears, and the voice deepens. There is rapid somatic maturation, resulting in premature epiphyseal closure and short adult stature. Although the internal genitalia are female, breast development and menstruation do not occur unless the excessive androgen production is suppressed by adequate steroid therapy.

In the male without salt wasting, the chief clinical manifestations are those of isosexual precocity. The infant appears normal at birth, but signs of sexual and somatic precocity appear within the first 2 to 3 years of life. Although the testes remain normal in size, enlargement of the penis, scrotum, and prostate occur, accompanied by the appearance of pubic hair, acne, and deepening of the voice. The musculature is well developed (prompting the descriptive term “little Hercules”), and bone age is more advanced than appropriate for the chronologic age. The syndrome often goes unrecognized in the non–salt-wasting male until signs of androgen excess, such as accelerated height and precocious pubic hair, appear later in childhood.

In the non–salt-wasting male, two major long-term implications are short stature and infertility in 20% to 40%. Premature epiphyseal closure will result unless early medical control is instituted. This emphasizes the value of neonatal screening. Infertility has been noted in 30% of CAH males, often related to the finding of testicular adrenal rest tissue (TART) most reliably diagnosed with scrotal ultrasonography. These nodules, present in 25% to 30% of males with CAH, represent hypertrophy of adrenal rests caused by ACTH stimulation and, when associated with impaired fertility, warrant periodic scrotal ultrasonography, intensified glucocorticoid suppression, and possibly testis-sparing excision (Claahsen-van der Grinten et al., 2008). Some advocate sperm cryopreservation in postpubertal males with adrenal rest tumors. In addition, poor control of the disease in boys with classic CAH has been associated with small testes and infertility with reduced sperm counts (New and Wilson, 1999). This is caused by peripheral aromatization of excess androgen to estrogen that suppresses pituitary gonadotropins.

In classic 21-hydroxylase deficiency, plasma levels of progesterone and 17-hydroxyprogesterone are markedly elevated. Urinary levels of 17-ketosteroids and pregnanetriol are elevated. **The diagnosis may be made**

biochemically with the use of radioimmunoassay of plasma 17-hydroxyprogesterone. A pelvic ultrasound study demonstrating the presence of müllerian tissues is confirmatory. Some investigators have suggested that the finding of abnormally enlarged or "cerebriform"-appearing adrenal glands on neonatal ultrasonography, available before biochemical results, may represent the earliest diagnostic tool for CAH (Hernanz-Schulman et al., 2002).

More aggressive screening for 21-hydroxylase deficiency has provided considerable benefits. In one series, despite sexual ambiguity, one-third to one-half of the affected female newborns were not diagnosed as having 21-hydroxylase deficiency until they were identified by the screening test (Pang et al., 1985).

Nonclassic 21-hydroxylase deficiency represents an attenuated, late-onset form that is variable in clinical severity because of its partial deficiency of 21-hydroxylase and timing of onset. These patients have a 30% to 50% reduction in 21-hydroxylase enzymatic activity and have hyperandrogenism. New and Wilson (1999) found the nonclassic 21-hydroxylase deficiency to be the most common autosomal recessive disorder in humans, with an incidence of 1 in 100, based on the heterogeneous population of New York City. The presenting symptoms in females are commonly hirsutism and oligomenorrhea, male pattern baldness, and polycystic ovaries. In men with the nonclassic form of 21-hydroxylase deficiency, oligospermia and subfertility have been presenting features, and reversal of infertility with glucocorticoid therapy has been reported. Typically, lower doses of glucocorticoid are required for management of the nonclassic form of CAH.

A deficiency of 11β-hydroxylase accounts for roughly 5% of cases of CAH. Both classic and mild forms have been recognized. Unlike 21-hydroxylase, 11β-hydroxylase is not linked to human leukocyte antigen. The defect results from mutations in the *CYP11B1* gene located on the long arm of chromosome 8 (Merke et al., 1998). Like 21-hydroxylase deficiency, the nonclassic variant of 11β-hydroxylase deficiency (late onset) is characterized by signs and symptoms of androgen excess in childhood or adolescence. **Hypertension is a common finding in patients with this type of CAH, and it is believed to be secondary to increased serum levels of deoxycorticosterone (DOC).** Although most patients are hypertensive, some are normotensive and others experience only intermittent hypertension. Marked virilization occurs in the severe form of the defect and may be as severe as in those patients with a 21-hydroxylase deficiency. In the late-onset form, mild virilization occurs in prepubertal and postpubertal patients.

The diagnosis of 11β-hydroxylase deficiency can be confirmed by finding increased plasma levels of 11-deoxycortisol and 11-DOC. The treatment with glucocorticoids is identical to that of patients with 21-hydroxylase deficiency.

The least common enzyme deficiency responsible for a virilizing form of CAH is 3β-hydroxysteroid dehydrogenase. This deficiency affects the early steps in steroid biosynthesis in both adrenal glands and gonads, resulting in inability to convert 3β-hydroxysteroids to 3-ketosteroids. As a result, the severe form leads to impaired synthesis of aldosterone, cortisol, and sex steroids. Affected females exhibit mild clitoromegaly and labial fusion accompanied by symptoms of aldosterone and cortisol deficiency.

Two homologous genes have been identified for 3β-hydroxysteroid dehydrogenase, both of which contain four exons (Merke et al., 1998). A number of mutations giving rise to the syndrome have been described. This defect has an autosomal recessive inheritance pattern and is heterogeneous in its biochemical and clinical appearance. A non–salt-losing form and mild- and late-onset forms have been described, although the nonclassic form appears to be exceedingly rare.

The diagnosis of 3β-hydroxysteroid dehydrogenase is based on finding increased serum levels of 17-hydroxypregnenolone and dehydroepiandrosterone (DHEA). The pelvic ultrasound evaluation, confirming presence of müllerian tissue, would be supportive. Treatment is similar to that of patients with 21-hydroxylase deficiency.

Currently, one of the most exciting aspects of CAH is the capability of diagnosing and treating the disorder prenatally. **Prenatal diagnosis of CAH in the at-risk fetus was initially made by a measurement of amniotic fluid for 17-hydroxyprogesterone at 16 to 17 weeks' gestation** (Laue and Rennert, 1995). Currently, the diagnosis is made during the first trimester by HLA genotyping or by DNA analysis of genes within the HLA complex in cells obtained by chorionic villus sampling at 9 to 11 weeks' gestation (Hughes, 2002). **Treatment of the mother is with dexamethasone, which crosses the placenta and suppresses fetal secretion of ACTH, thereby preventing virilization of the genitalia.** However, treatment should be instituted as soon as pregnancy is confirmed, and no later than 9 weeks after the last menstrual period, before initial development of the external genitalia (Nimkarn and New, 2007). There are certain complexities to this form of management. The diagnosis of CAH in the fetus may be determined on chorionic villous cells or on cells from amniotic fluid for families in which a prior member was affected. **Therefore, it is not possible to confirm the diagnosis before therapy is initiated.** Because virilization is not a concern with the male fetus and three of four female fetuses at risk are unaffected, given the autosomal recessive pattern of inheritance, seven of eight fetuses may be treated unnecessarily. Therefore, one goal in therapy has been earlier diagnosis to avoid unnecessary treatment. The incorporation of PCR analysis of free fetal DNA from circulating trophoblastic cells in the maternal circulation has allowed detection of Y chromosome, thus avoiding treatment of males (Rijnders et al., 2001).

A number of series have established the effectiveness of prenatal treatment for CAH with dexamethasone in 85% of cases (Migeon, 1990; Pang et al., 1990; Speiser et al., 1990). In some neonates, there is no evidence of masculinization, suggesting totally successful therapy. In another group, there is milder masculinization than that noted in an affected sibling. Although compliance and timing of initiation of treatment have been variable from series to series, this heterogeneity of response to therapy raises intriguing questions about the mechanisms involved in virilization of the CAH fetus. In addition, prenatal treatment with dexamethasone has raised ethical concerns. **Although there is no arguing its ability to prevent androgen effects on the genitalia and potentially the brain of affected females, the long-term effects of prenatal dexamethasone treatment on unaffected fetuses remain an important concern.** A study by Meyer-Bahlburg et al. (2004a) demonstrated no cognitive or developmental motor impairment resulting from prenatal treatment of CAH fetuses, but others have suggested potential deleterious effects on verbal working memory, self-perceived scholastic competence, and increased social anxiety (Hirvikoski et al, 2007). More recently, Meyer-Bahlburg et al. (2012) confirmed no adverse effect of short-term prenatal dexamethasone exposure on working memory. However, long-term exposure was associated with slower mental processing. Because of these potential risks, Miller (2015) has strongly advocated the use of prenatal treatment for CAH only as an experimental therapy in large centers and under institutional review board scrutiny. In contrast, Wallensteen et al. (2018) reported no differences in adaptive functioning, behavioral/emotional problems, social anxiety, or temperament between dexamethasone-treated and control children and adolescents. Furthermore, Wallensteen et al. (2018) found no significant neuropsychological deficits when they examined first-trimester dexamethasone-exposed adults as compared with controls and suggest that deficits observed during childhood may improve with time. Long-term follow-up of former dexamethasone-treated fetuses is essential.

Hughes (2002) and others have emphasized the close correlation in CAH of genotype and phenotype. Hannah-Shmouni et al. (2017) recently noted a genotype-phenotype correlation in 90% of cases (Hannah-Shmouni et al, 2017). Certain genotypes were more frequent in specific ethnic groups. This has a number of practical implications. Molecular biologists can now predict not only the risk for a couple having an affected child but also the likely clinical form of the disease. Therefore, genotypes of severe mutations would motivate prenatal treatment, whereas genotypes of less severe mutations would not. In addition, less severe genotypes in the newborn would allow for modification of corticosteroid treatment to minimize side effects.

The treatment of affected children with hydrocortisone in childhood and adolescence achieves a number of goals, as noted by Bongiovanni and Root (1963): “to supply the deficient hormone; to suppress pituitary ACTH secretion and hence adrenal androgens and clinical virilization; to forestall abnormally rapid somatic growth and osseous advance; to permit normal gonadal development; and to correct salt-water loss or hypertension in the complicated forms.” The required dose of glucocorticoid may be predicted by genotype, as noted by Hughes (2002), but should be adjusted for the individual patient based on bone age, linear growth, 24-hour excretion of ketosteroids, and clinical evidence of glucocorticoid deficiency or excess (Grumbach and Conte, 1998). The effectiveness of therapy may be assessed by measuring morning plasma 17-hydroxyprogesterone levels. Those children with the salt-losing form of the disease require increased salt intake and mineralocorticoid treatment in addition to hydrocortisone therapy. After control of electrolytes and blood pressure has been achieved in the acute setting, maintenance therapy with fludrocortisone should be instituted (Laue and Rennert, 1995; Grumbach and Conte, 1998). The administration of hydrocortisone and, when required, fludrocortisone (0.05–0.3 mg/day) is continued indefinitely in all patients (American Association of Pediatrics, 2000). Typically, patients are instructed to triple their oral dose of hydrocortisone during physically stressful events such as surgery or infection.

In significantly virilized females (who will not have been diagnosed and treated prenatally), it is appropriate to perform feminizing genitoplasty at 6–12 months of age, when a well-established course of medical therapy has been instituted, the risks of anesthesia have become minimal, and the child has grown large enough to make the procedure technically feasible (Passerini-Glazel, 1990). **Long-term fertility in males and feminization, menstruation, and fertility in females can be anticipated in the well-treated patient.** Indeed, this potential in even the most masculinized female CAH patient has provided support for feminizing genitoplasty in virtually all 46,XX CAH patients. Although female gender rearing is supported by the 2006 Consensus Statement, it has been challenged by Lee and Husmann for those patients with 46,XX CAH who appear unambiguously male for whom they recommend consideration of male gender assignment (Lee et al, 2010).

An important area of research has been the potential imprinting of the brain by elevated prenatal androgen levels. A number of studies confirm that prenatal hyperandrogenization is associated with masculinization of gender-related behavior but not masculinization of gender identity. Meyer-Bahlburg et al. (Dessens et al, 2005; Meyer-Bahlburg et al, 2004b, 2008) noted a close correlation between hormonal abnormalities as a function of severity of enzyme deficiency with sexual orientation (homosexuality, bisexuality rates). Furthermore, Berenbaum et al. (2003, 2004) noted that in females with CAH and virilized genitalia psychological development is not compromised in those who are reared as females and receive good medical care. Meyer-Bahlburg et al. (2004a) noted in 46,XX CAH girls that marked masculinization of gender-related behavior in prenatally hyperandrogenized CAH girls was not associated with masculinization of gender identity. However, this has been challenged by recent work noting increased cross-gender identification in CAH girls that appears to occur in proportion to physiologic evidence of virilization (Pasterski et al., 2015). Indeed, proper psychological support should be a component of long-term follow-up.

In an interesting finding, both male and female patients with classic CAH have been noted on magnetic resonance imaging to have smaller amygdala volumes than controls and altered amygdala function. The amygdala, regulated by glucocorticoids, is important in processing emotion (Ernst et al., 2007).

An intriguing area of surgical innovation in the management of CAH has been the experimental use of “prophylactic” adrenalectomy for selected patients. This approach is based on the premise that in certain patients it is more difficult to maintain adrenal suppression than to prevent adrenal crises. Clinically, these patients are the salt losers and extremely virilized females. For those with this most severe form of 21-hydroxylase deficiency, adequate suppression of adrenal production has required significant degrees of hypercortisolism, associated with poor growth, obesity, and infertility (in 40%).

For the 25% of CAH patients who completely lack 21-hydroxylase enzyme activity and therefore produce neither cortisol nor aldosterone, adrenalectomy may be a practical approach (VanWyk et al., 1996). In general, these patients may be identified genotypically as homozygotes or compound heterozygotes for “null alleles” of the *CYP21* gene (VanWyk et al., 1996). In a series of 18 patients with long-term follow-up, VanWyk and Ritzen (2003) noted bilateral adrenalectomy to be safe and effective in managing severe forms of CAH in which patients repeatedly escaped adrenal suppression. Most of these patients reported a better quality of life after bilateral adrenalectomy. Bilateral adrenalectomy proved more successful for those patients pursuing fertility rather than control of obesity and hyperandrogenism (Ogilvie et al., 2006).

Although these patients are rendered Addisonian by this surgery, those with the most severe form of CAH would have a poor intrinsic adrenal response to metabolic stress (Gunther et al., 1997). One theoretical disadvantage of this approach is that if gene therapy were to one day allow functional *CYP21* genes to be introduced into adrenal cortical tissue, adrenalectomized patients would not be candidates for such therapy (VanWyk et al., 1996).

Males with congenital adrenal hyperplasia must be followed for testicular adrenal rest tumors (TARTs) as a potential cause of infertility. This is ideally performed with annual screening testicular ultrasounds (Kang, 2011).

46,XX DSD (Masculinized Female) Secondary to Maternal Androgens and Progestins and Maternal Tumors

The masculinization of a female fetus as a result of maternal administration of synthetic progestational agents or androgens is a rare occurrence; lessons have been learned from prior unfortunate experiences. Historically, progestational agents were used to prevent threatened abortion. In one large series, masculinization occurred in 2% of female infants whose mothers were treated with progestins during pregnancy (Ishizura et al., 1962). In addition, danazol, a testosterone derivative used to treat endometriosis, has been associated with virilization of the female fetus. **The degree to which any androgen or progestational agent affects female fetal development is a function of the strength of the agent, its maternal dosage, and timing and duration of administration** (Bongiovanni and McFadden, 1960).

Very rarely, a maternal ovarian or adrenal tumor has virilizing effects on a female fetus. More typically, such a tumor has virilizing effects on the mother but no apparent effect on the fetus. Ovarian tumors that have resulted in masculinization of the female fetus include arrhenoblastoma, hilar cell tumor, lipoid cell tumor, ovarian stromal cell tumor, luteoma of pregnancy, and Krukenberg tumor (Calaf et al., 1994).

Rarer still are maternal adrenal tumors (adrenocortical carcinoma and adenoma), which have masculinizing effects on the female fetus.

Aromatase deficiency represents an even rarer cause of transplacental transport of excess androgens to the fetus. The cytochrome P450 aromatase enzyme catalyzes the conversion of androgens to estrogens. Normally, weak androgens produced by the fetal adrenal gland are converted to estrogens by placental aromatase and pass to the maternal circulation. Mutations of the *CYP19* aromatase gene can result in profound virilization of the female fetus and mother during pregnancy. Although maternal virilization resolves postnatally, it recurs in subsequent pregnancies.

In any case of exogenous androgen effect on a female fetus, normal endocrine status is recognized postnatally, and management is confined to external genital reconstruction, as required.

46,XY DSD (Undermasculinized Male)

The term *46,XY DSD (undermasculinized male)* refers to 46,XY individuals with differentiated testes who exhibit varying degrees of feminization phenotypically. Impaired male differentiation in these patients is secondary to inadequate secretion of testosterone by the testes at the necessary period in development, inability of target tissue to respond to androgen appropriately, or impaired production or action of AMH.

Leydig Cell Aplasia (Luteinizing Hormone Receptor Abnormality)

Leydig cell aplasia as a cause of undermasculinization of the male was first reported in 1976 by Berthezene et al. (Berthezene et al.,1976). **In its pure form, this rare disorder is characterized by a normal 46,XY male karyotype associated with a normal-appearing female phenotype. Typically, testes are palpable in the inguinal canals or labia majora.** On investigation, there are no müllerian structures, and the vagina is short. A low testosterone level is noted in conjunction with an elevated LH concentration. **The absence of a rise in serum testosterone level after hCG stimulation is characteristic of this disorder** (Brown et al., 1978). Physiologically, this disorder represents a spectrum between absent Leydig cells and Leydig cells with abnormal LH receptor (David et al., 1984). Because a number of inactivating mutations have been found in the LH receptor gene, a correlation can be made between the phenotype of patients with Leydig cell hypoplasia and the activity of their LH receptor alleles (Richter-Unruh et al., 2004). It is transmitted as an autosomal recessive trait expressed only in males. Incomplete forms of the syndrome occur, with the mildest form being expressed as primary hypogonadism with normal male external genitalia (Lee et al., 1982).

The clinical diagnosis of Leydig cell aplasia, or LH receptor abnormality, is typically made as a result of sexual infantilism and the absence of development of secondary sexual characteristics or the discovery of palpable gonads in the inguinal canal or labia on physical examination (Arnholt et al., 1985). The differential diagnosis includes androgen insensitivity syndrome or a terminal defect in androgen synthesis. The histology of the abnormal testes demonstrates absence of Leydig cells in intratubular spaces with normal Sertoli cells.

Disorders of Testosterone Biosynthesis

A defect in any of the five enzymes required for the conversion of cholesterol to testosterone can cause incomplete (or absent) virilization of the male fetus during embryogenesis. The first three enzymes (cholesterol side-chain cleavage enzyme, 3β-hydroxysteroid dehydrogenase, and 17β-hydroxylase) are present in both adrenal glands and testes. **Therefore, their deficiency results in impaired synthesis of glucocorticoids and mineralocorticoids in addition to testosterone.** For all five enzyme deficiencies, the pattern of inheritance is autosomal recessive.

Congenital Lipoid Adrenal Hyperplasia (StAR Deficiency).

The first step in gonadal and adrenal steroidogenesis is conversion of cholesterol to pregnenolone, which is mediated by a single cholesterol side-chain cleavage enzyme known as 450SCC (previously known as 20-22 desmolase). A defect in this enzyme, first described by Prader and Gurtner in 1955, was believed to result in the rare condition congenital lipoid adrenal hyperplasia, so named because the adrenal glands became large and lipid laden. **However, more recent evidence suggests that a defect in cholesterol transport is usually etiologically responsible** (Sahakitrungruang, 2015). The steroidogenic acute regulatory (StAR) protein stimulates cholesterol transport from the outer to the inner mitochondrial membrane (site of the cholesterol side-chain cleavage complex). This appears to be the rate-limiting step in acute steroid synthesis.

Over 40 StAR mutations causing lipoid adrenal hyperplasia have been found in various ethnic groups but are most commonly reported in patients of Japanese, Korean, and Palestinian origin (Bhangoo et al., 2005). Affected 46,XY individuals have female or ambiguous external genitalia with a blind-ending vaginal pouch; intra-abdominal, inguinal, or labial testes; and absence of müllerian structures, consistent with functioning Sertoli cells (Hauffa et al., 1985). Wolffian ducts are present but rudimentary. Infants often present in the first few weeks of life with severe adrenal insufficiency and salt wasting, but delayed presentation has been reported (Lekarev et al., 2012).

A diagnosis of StAR (cholesterol side-chain cleavage enzyme) deficiency should be entertained in any neonate with nonvirilized female external genitalia and evidence of cortisol and aldosterone deficiency with hyponatremia, hyperkalemia, and metabolic acidosis. Abdominal computed tomography demonstrates large, lipid-laden adrenal glands.

Management is similar to that for 21-hydroxylase deficiency. Classically, 46,XY patients with this disorder have been raised as females and have undergone gonadectomy (Laue and Rennert, 1995). Because testosterone production was never significant, brain imprinting is not a factor in gender assignment. But, phenotype can be quite variable, such that partial virilization or even normal male genitalia may result (Lekarev et al., 2012).

Cytochrome P450 Oxidoreductase Deficiency.

Cytochrome P450 oxidoreductase (POR) deficiency has been added to the causes of both 46XY and 46XX DSD. POR is a cofactor to all microsomal P450 enzymes, including 17-hydroxylase, 17,20-lyase, 21-hydroxylase, and aromatase. The condition emerged as a distinct entity through the realization that apparent combined deficiency of 17-hydroxylase and 21-hydroxylase enzymes is a single disorder caused by lack of POR, a membrane-bound flavoprotein that plays a central role in electron transfer from NADPH to P450 enzymes. It was originally characterized in patients with Antley-Bixler syndrome (a skeletal dysplasia syndrome) in whom some had ambiguous genitalia and abnormal steroidogenesis. Subsequently, it has become clear that POR deficiency can cause DSD unassociated with skeletal dysplasia and characteristics of Antley-Bixler syndrome (Hughes, 2008).

3β-Hydroxysteroid Dehydrogenase Deficiency.

3β-Hydroxysteroid dehydrogenase catalyzes the 3β-hydroxysteroids (pregnenolone, 17-hydroxypregnenolone, and DHEA) to the three ketosteroids, progesterone, 17-hydroxyprogesterone, and androstenedione. A congenital deficiency of 3β-hydroxysteroid dehydrogenase was first described by Bongiovanni in 1962.

Affected individuals present with varying degrees of incomplete masculinization resulting from a block in testosterone biosynthesis and with salt-wasting adrenal insufficiency resulting from impaired synthesis of aldosterone and cortisol. The lack of salt-retaining hormone and cortisol results in a salt-losing crisis soon after birth. However, partial deficiencies associated with severe salt wasting occur, consistent with genetic heterogeneity. Two isoenzymes, type 1 and type 2 3β-hydroxysteroid dehydrogenase, are involved in steroid biosynthesis. These enzymes are encoded by two genes, *HSD3B1* and *HSD3B2,* localized to chromosome 1 at locus p11–p13 (Chang et al., 1993). Classical 3β-hydroxysteroid dehydrogenase deficiency results from inactivating mutations, 37 of which have been identified, in the *HSD3B2* gene (Welzel et al., 2008).

Males with this deficiency usually exhibit incomplete virilization of the external genitalia, with a small phallus, hypospadias with labioscrotal fusion, a urogenital sinus, and a blind-ending vaginal pouch. Testes are often scrotal, and wolffian ducts develop normally. As with other defects in testosterone biosynthesis, in which normal Sertoli cell function is preserved, müllerian structures are absent.

The diagnosis should be considered in 46,XY males with ambiguous genitalia and signs of adrenal insufficiency. Endocrine study demonstrating increased levels of 3β-hydroxysteroids confirms the diagnosis.

Management of 3β-hydroxysteroid dehydrogenase is similar to that for patients with 21-hydroxylase deficiency. The chronic sequelae of exogenous glucocorticoid excess with reduced quality of life for these severe CAH patients has been well documented (Benkert et al., 2015).

17α-Hydroxylase Deficiency.

17α-Hydroxylase catalyzes the conversion of pregnenolone and progesterone to 17α-hydroxypregnenolone and 17-hydroxyprogesterone, respectively, in adrenal and gonadal steroidogenesis. The first case of male pseudohermaphroditism caused by this enzyme deficiency was reported in 1970 by New (1970). The gene for this enzyme has been localized to chromosome 10 (Laue and Rennert, 1995).

Affected 46,XY individuals usually have female external genitalia with absent to slight masculinization. **A deficiency in 17α-hydroxylase activity impairs cortisol production, causing ACTH hypersecretion and resulting in increased levels of DOC, corticosterone, and 18-hydroxycorticosterone in the adrenal glands. These compounds with mineralocorticoid activity produce excess salt and water retention, hypertension, and hypokalemia.**

The phenotype of affected individuals varies from female with external genitalia with a blind-ending vaginal pouch to male with perineal hypospadias and chordee. The diagnosis should be considered in an undervirilized male with hypertension. Endocrine laboratory evaluation demonstrates elevated serum progesterone, DOC, corticosterone, 18-hydroxycorticosterone, and ACTH.

Therapy with glucocorticoid replacement brings blood pressure and hypokalemia back to normal by suppressing ACTH and hence adrenal cortical stimulation. Some patients have been raised as females with gonadectomy and estrogen replacement at puberty. In partial forms, typically with reasonable phallic size, patients may be raised as male with testosterone replacement at puberty. **Fertility has not been reported in patients with testosterone biosynthetic defects, and inadequate testosterone production makes androgen imprinting a less significant issue for these patients.** Therefore, the phenotype may dictate gender assignment.

17,20-Lyase Deficiency.

The enzyme 17,20-lyase has been demonstrated to be related to 17α-hydroxylase in that the activities of both are linked to the same gene product on chromosome 10 (Laue and Rennert, 1995). However, in some patients with the genetic defect, both biologic activities are absent, but with others only the 17,20-lyase function appears deficient. Zachmann et al. first described this clinical entity in 1972.

In cases in which the deficiency primarily involves 17,20-lyase, cortisol and ACTH secretion are normal. Aldosterone is secreted normally, and hypertension does not result. **However, impaired biosynthesis of testosterone in the 46,XY individual results typically in ambiguous rather than totally female genitalia at birth.** The deficient masculinization of the external genitalia can range from severe, resulting in a female gender assignment in the neonate, to mild, resulting only in hypospadias. At puberty, the secretion of testicular androgen remains low. Zachmann et al. (1982) have postulated that there are two types of 17,20-lyase deficiency—one that is partial and another that is a complete defect.

The diagnosis may be suspected in undervirilized males with absent müllerian derivatives and no defect in glucocorticoid or mineralocorticoid synthesis. At the time of expected pubertal development, patients may present with failure to develop secondary sexual characteristics and elevated gonadotropin levels. The diagnosis may be made prepubertally using hCG and ACTH stimulation.

Management entails plastic reconstruction of the external genitalia and appropriate sex steroid replacement at puberty.

17β-Hydroxysteroid Oxidoreductase Deficiency.

This last enzyme in the testosterone biosynthetic pathway catalyzes the conversion of androstenedione to testosterone, DHEA to androstenediol, and estrone to estradiol. Male undervirilization resulting from a deficiency in 17β-hydroxysteroid oxidoreductase was first described by Saez et al. in 1971.

Clinically, this is the most interesting enzymatic defect in testosterone biosynthesis in its similarities to 5α-reductase deficiency. At birth, affected individuals appear to have a normal female phenotype, without significant evidence of virilization. Therefore, a female gender assignment is usually made. However, these individuals have well-differentiated testes located intra-abdominally, inguinally, or in the labia and no müllerian structures. Surprisingly, wolffian ducts are normally developed, which may be secondary to the action of androstenedione or minimal amounts of testosterone produced during embryogenesis (Boehmer et al., 2001). **At puberty, there is phallic growth and progressive development of male secondary sexual characteristics.** These include increased muscle mass and development of pubic, axillary, and facial and body hair with male distribution. Gynecomastia may occur, and the testes may become palpable (Saez et al., 1972). In some cases, gender reassignment to male has been reported (Imperato-McGinley et al, 1979; Rosler and Kohn, 1983).

The late onset of virilization is related to the pubertal increase in gonadotropin production, which may partially overcome the block in testosterone biosynthesis.

There is a characteristic hormonal profile in this disorder. In the prepubertal patient, plasma androstenedione and estrone levels may not be increased. At puberty, androstenedione, the immediate precursor of testosterone, is increased to 10 to 15 times the normal plasma concentration (Virdis and Saenger, 1984). Earlier precursors are within normal levels. Plasma testosterone is in the low-normal range. Serum levels of LH and FSH are markedly elevated, typically four to six times normal.

As a result of biochemical characterization and molecular cloning, 14 different 17β-hydroxysteroid dehydrogenase isozymes have been identified to date (Lukacik et al., 2006). **The type III 17β-hydroxysteroid dehydrogenase isozyme, cloned by Andersson et al. (1997), catalyzes the biosynthesis of testosterone from androstenedione. A mutation involving the *HSD17B3* gene, mapped to chromosome 9q22, is responsible for male undervirilization.** The type III isozyme is apparently expressed early in utero and is responsible for testosterone biosynthesis during the critical period of sexual development, based on the observation that male adults homozygous for 17β-hydroxysteroid dehydrogenase type III gene defects have ambiguous genitalia (Zhu et al., 1998).

The diagnosis is rarely made in the neonatal period. It may become apparent on discovery of a testis during a hernia repair in infancy or childhood. An hCG stimulation test resulting in an increased testosterone-to-androstenedione ratio would confirm the diagnosis and differentiate this condition from androgen insensitivity (Ahmed et al., 2000). **The primary management issue for patients with 17β-hydroxysteroid oxidoreductase deficiency has been gender assignment.** At this early stage, maintenance of the female sex of rearing with gonadectomy is usually elected. If the diagnosis is not made until puberty, when dramatic changes in virilization occur, certain families prefer a gender change to male. Cohen-Kettenis found gender role changes in 39% to 64% of 17β-hydroxysteroid oxidoreductase deficiency patients raised as female (Cohen-Kettenis, 2005). In an Arab cohort of 22 patients, Sobel et al. (2004) noted seven to undergo spontaneous gender role reversal to male without parental consent or psychiatric intervention. Traditionally, this decision has been strongly culturally influenced.

If a female sex of rearing is elected, gonadectomy, plastic reconstruction of the genitalia as necessary, and estrogen replacement therapy at puberty are indicated. For the patient maintained in the male gender, orchidopexy and reconstruction of the external genitalia are required. This entails hypospadias repair and chordee correction, which can be quite successful. However, phallic size remains small, and infertility is the rule. Some have suggested that childhood treatment with intramuscular testosterone may result in a larger phallus (Sobel and Imperato-McGinley, 2004). Usually endogenous androgen levels are adequate long term.

Two hypotheses have been proposed to explain the frequency of gender change from female to male with this enzyme deficiency, particularly among the cohort of Arab male pseudohermaphrodites with 17β-hydroxysteroid dehydrogenase type III deficiency. One entails the potential male imprinting of the brain in utero caused by the conversion of androstenedione to estrone; this theory is supported by studies in rats and rabbits demonstrating that administration of estrogen or androstenedione is capable of inducing male sexual behavior (Reddy et al., 1974). The second is the possibility that 17β-hydroxysteroid dehydrogenase activity is not deficient in the brain, its effect being mediated by the conversion of androstenedione to testosterone or estrogen (Imperato-McGinley et al., 1979).

Androgen Receptor and Postreceptor Defects

Disorders of androgen receptor function represent the most common definable cause of 46,XY DSD and the undervirilized male. These patients characteristically have a 46,XY karyotype and testes and present with a spectrum of phenotypic abnormalities that vary from complete external feminization (syndrome of complete androgen insensitivity), to ambiguous genitalia (partial androgen insensitivity syndrome), to the phenotypically infertile male. Although the clinical presentations vary according to the severity of the disorder, the pathophysiology is similar (Wiener et al., 1997).

Syndrome of Complete Androgen Insensitivity.

The syndrome of complete androgen insensitivity is characterized clinically by a 46,XY karyotype, bilateral testes, female-appearing external genitalia, and absence of müllerian derivatives. Wilkins first suggested in 1950 that the clinical features of this syndrome were the result of androgen resistance. This condition has an incidence of 1 in 20,000 to 1 in 60,000 males, and it is transmitted as an X-linked trait.

The androgen receptor regulates the transcription of other specific genes, once activated by testosterone or DHT. This results in new mRNA synthesis from the downstream genes and protein production. The androgen receptor has been mapped to the X chromosome at Xq11–12, spanning 90 kb and comprising eight exons (Brown et al., 1989; Hiort and Holterhus, 2003). Males have only one copy of this gene. A mutation of the gene is identified in 95% of cases of complete androgen insensitivity (Hughes et al., 2012). **The identifiable molecular alterations of the androgen receptor gene cannot predict the resulting phenotype of the affected individual unless there is total loss of the receptor, which occurs in only 1% of all patients** (Quigley et al, 1995).

Patients with complete androgen insensitivity have a normal female phenotype with the exception of diminished axillary and pubic hair. Their breast development and body habitus are feminine in character, and their external genitalia are unequivocally female, although the vagina is short and blind ending. It had previously been believed that in-utero resistance to testosterone action prevented stabilization of the wolffian ducts. Hannema et al. (2004), however, demonstrated wolffian duct derivatives in cases of complete androgen insensitivity. In 42% of patients, screening of the paratesticular area revealed well-developed epididymis and/or vasa deferentia. The mutations found in these patients entailed a single amino acid substitution in the androgen receptor ligand-binding domain, rather than frameshift mutations, premature stop codons, or mutations in the DNA-binding domain, all of which were associated with absence of well-developed wolffian duct structures. These investigators suggest that mutant receptors with residual activity in vivo stimulate wolffian duct development. As a result, they should be classified as having *severe* rather than complete androgen insensitivity. Because the fetal testes secrete AMH, müllerian structures are absent. The testes may be found in the labia, inguinal canal, or abdomen.

These patients are rarely diagnosed in the neonatal period, unless a prenatal diagnosis is made on the basis of female phenotype and 46,XY karyotype on amniocentesis. With the increase in prenatal diagnostics, this is becoming a more common occurrence (Hughes and Patterson, 1994). More typically, however, the diagnosis is made as a result of primary amenorrhea or the finding of a testis at inguinal herniorrhaphy. Fifty percent of patients with complete (severe) androgen insensitivity syndrome have an inguinal hernia (Conte and Grumbach, 1989). Conversely, 1% to 2% of apparently female infants with inguinal hernia are found to have a 46,XY karyotype and complete androgen insensitivity syndrome (Wiener et al., 1997; Barthold et al., 2000). Therefore, routine vaginoscopy to confirm the presence of a cervix or endoscopy through a hernia sac to identify an intra-abdominal testis at the time of inguinal herniorrhaphy in female patients is a prudent maneuver. Histologically, the testes exhibit incomplete or absent spermatogenesis, with normal or hyperplastic Leydig cells. They are comparable to immature, cryptorchid testes.

Endocrine evaluation in the neonatal period demonstrates normal male levels of testosterone, DHT, and gonadotropins. At puberty, gonadotropin levels rise, leading to increased levels of plasma estradiol and also peripheral aromatization of testosterone, which result in feminization, including breast development.

Several types of mutant receptor abnormality that would account for this syndrome have been described, including (1) a decreased amount of apparently normal receptor; (2) absence of receptor binding; (3) a qualitatively abnormal receptor (thermolabile, or unstable); and (4) other “receptor-positive” forms, including increased rate of dissociation of steroid receptor complex, defective upregulation of the androgen receptor, decreased affinity of ligand binding, and impaired nuclear retention of the ligand (Grumbach and Conte, 1998). In general, the severity of the defect in androgen receptor (quantity or quality) correlates with the phenotype. In addition, Hughes (2001) noted the absence of coregulator proteins, without the absence of the androgen receptor, in cases of complete androgen insensitivity, suggesting that for androgen effects to be optimal an integrated array of transcriptional factors, coregulators, and ligands is required.

The diagnosis of complete (severe) androgen insensitivity may readily be made in the postpubertal patient on the basis of clinical and hormonal findings of amenorrhea, absence of pubic hair, or inguinal hernias containing testes. It is confirmed by a 46,XY karyotype and a normal male androgen and gonadotropin profile. Pelvic ultrasound examination confirms the absence of müllerian tissue, and a vaginal examination confirms a blind-ending vagina without a cervix.

In the prepubertal child, one may use PCR to characterize the androgen receptor gene in DNA obtained from a venous blood sample to detect a genetic mutation responsible for androgen insensitivity syndrome.

Management of complete (severe) androgen insensitivity relates primarily to the optimal timing of gonadectomy. Because the testes produce estradiol, which results in the appropriate changes for the female phenotype, it is considered by many preferable to leave the testes in situ until puberty is complete. Potential exceptions to the policy of delayed gonadectomy are palpable testes or testes associated with an inguinal hernia. One important caveat in deciding to leave the testes in situ is the need to confirm with absolute certainty that complete rather than partial androgen insensitivity exists by PCR characterization of the androgen receptor gene in venous blood DNA. If an incomplete form should exist, virilization at puberty could result (Batch et al.,

1993).

A competing concern for retention of testicular tissue is the potential for malignant degeneration of the testes. In prepubertal patients with complete androgen insensitivity with a retained testis, the risk for development of a testis tumor—usually gonadoblastoma, dysgerminoma, or seminoma—is thought to be 0.8% to 2%, only slightly higher than for a cryptorchid testis (Manuel et al., 1976; Muller and Skakkebaek, 1984; Hughes, 2012). Therefore, in general, delayed gonadectomy after puberty is believed to be safe (Cools et al., 2006). Accurate figures to predict adult gonadal tumor risk in CAIS are sparse as there have been too few adult gonadectomized patients to truly assess risk. Chaudhry et al. suggested a combined premalignant and malignant histology prevalence of 6% based on a review of 133 patients in all age ranges, and Cools et al. noted an incidence of premalignant histology of 14% of 42 women with CAIS ranging from 14 to 54 years of age (Chaudhry et al, 2017; Cools et al., 2017) Because of the complexity of managing the CAIS patient, Hughes has advocated an individualized and holistic approach for each patient (Hughes, 2012).

After orchiectomy, cyclic estrogen/progestin therapy is begun. The majority of patients have successful treatment of their short vagina with progressive dilation (Ismail-Pratt et al., 2007). Some patients may benefit from vaginoplasty (Boehmer et al., 2001). **Currently, all studies of patients with complete androgen insensitivity support an unequivocal female gender identity, consistent with androgen resistance of brain tissue as well.** In one study, no statistical differences were found between the complete androgen insensitivity group and normal controls in any quality-of-life or gender-related behavior criterion (Hines et al., 2003). To date, there has been no report of a patient with complete androgen insensitivity raised as a female who needed gender reassignment to male (Meyer-Bahlburg, 1999). In any event, age-appropriate psychological counseling is an important component of management in the androgen insensitivity syndromes.

Syndrome of Partial Androgen Resistance.

The syndrome of partial androgen resistance includes syndromes that were once thought to represent separate entities: Reifenstein, Gilbert-Dreyfus, Rosewater, and Lubs syndromes (Griffin, 1992). **These are X-linked disorders** of incomplete masculinization that represent a spectrum of phenotypic abnormalities. **The major finding is ambiguity of the external genitalia to varying degrees.** The partial form of androgen insensitivity may be expressed variably, even within the same family. **The classic phenotype is that of a male with perineoscrotal hypospadias, cryptorchidism, rudimentary wolffian duct structures, gynecomastia, and infertility. However, the phenotypic spectrum can range from hypospadias and a pseudovagina to gynecomastia and azoospermia** (Wilson et al., 1974). The differential diagnosis includes 5α-reductase deficiency and 17β-hydroxysteroid dehydrogenase. The endocrine profile of partial androgen insensitivity syndrome is similar to that of the complete androgen insensitivity syndrome. At puberty, gynecomastia may develop. The phallus may enlarge slightly, but it remains small.

To date, over 800 mutations in the androgen receptor gene have been discovered (Hughes, 2012). It has been well recognized in PAIS that these mutations produce a diversity of phenotypes between and within affected families, consistent with additional factors that modulate responsiveness to androgen.

The diagnosis of PAIS can be difficult. In the neonatal period, it may be made in the setting of a 46,XY karyotype, ambiguous external genitalia, and absent müllerian structures on pelvic ultrasound. Endocrine evaluation confirms normal male levels of testosterone and gonadotropins, and a normal testosterone/DHT ratio. An hCG stimulation test and characterization of the androgen receptor gene in serum DNA by PCR should confirm the diagnosis. A family history consistent with X-linked inheritance of ambiguous genitalia is of great assistance. A course of androgen injections in early infancy is often used to assess androgen responsiveness, which can aid in gender assignment.

Management must be individualized depending on the degree of genital ambiguity. In patients assigned a female gender, gonadectomy and surgical reconstruction of the external genitalia are indicated; at puberty, estrogen/progestin replacement is instituted. The majority of PAIS patients raised as males require treatment of cryptorchidism, reduction of gynecomastia, and genital reconstruction. Phallic size remains small, however, and the effects of supraphysiologic doses of testosterone have been disappointing (Migeon et al., 1994). A study by Szafran et al. presented a novel high content analysis (HCA) approach to study androgen receptor function at a single-cell level in genital fibroblasts (Szafran et al., 2009). This could help individualize medical therapy. The risk for gonadal tumor may be somewhat lower than in complete androgen insensitivity syndrome (10%), and there is an increased risk for male breast cancer with partial androgen insensitivity syndrome (Hughes, 2006; Cools et al., 2017). Of importance in considering gender assignment in patients with partial androgen insensitivity is the recognition that the receptor defect affecting the external genitalia appears to affect brain receptors for testosterone similarly. Unfortunately, because of the distinct phenotypic variability, even within families, gender assignment of patients with partial androgen insensitivity syndrome cannot be based on the specifically identified androgen receptor gene (Boehmer et al., 2001). The study by Melo et al. (2003) of 11 patients with partial androgen insensitivity syndrome (5 raised female, 6 raised male) demonstrated gender of rearing to be consistent with adult gender role. This suggests the possibility that in the setting of inadequate androgen imprinting of the fetal brain, sex of rearing may predominate in determination of gender identity. Unfortunately, this has not consistently proven to be the case.

Unfortunately, long-term outcome data in the management of patients with partial androgen insensitivity syndrome is limited. In a study of 14 patients with partial androgen insensitivity syndrome, Migeon et al. noted that 23% were dissatisfied with neonatal gender assignment irrespective of current status as male or female (Migeon et al., 2002). Another study of 15 postpubertal males with partial androgen insensitivity syndrome documented major impairment in sexual function in all (Bouvattier et al, 2006). However, Mazur (2005) found that only 9% of patients with partial androgen insensitivity syndrome self-initiated a gender reassignment.

The current recommendation for partial androgen insensitivity syndrome is to allow virilization of the external genitalia to serve as a guide in gender assignment, in that this may be the best means of assessing androgen imprinting of the brain, for lack of a more precise marker (Sobel and Imperato-McGinley, 2004).

Mild Androgen Insensitivity Syndrome.

A relatively new classification is that of mild androgen insensitivity syndrome discovered in the course of investigations for male factor infertility. Studies have demonstrated a variety of mutations, usually quite discrete within the androgen receptor gene, to account for the infertility (Hiort and Holterhus, 2003). Men with this syndrome may be normal phenotypically or have a history of mild hypospadias repair and development of gynecomastia but are azoospermic or severely oligospermic. They have been found to have normal to elevated serum testosterone levels with normal to elevated LH levels. This suggests that infertility in otherwise normal males may be the clinical manifestation of partial androgen insensitivity, representing the far end of a variable phenotypic spectrum. Knockout experiments of the androgen receptor in mice have demonstrated a functional receptor expressed in Sertoli and Leydig cells that is essential for normal spermatogenesis (Hughes et al., 2012).

5α-Reductase Deficiency

The disorder of 5α-reductase deficiency is one of the most fascinating forms of male undervirilization. The clinical presentation of this enzyme disorder was actually predicted in 1972, before the description of such patients in 1974 by Walsh and Imperato-McGinley et al. (Wilson, 1972; Imperato-McGinley et al., 1974; Walsh et al., 1974). Extensive characterization of the disease has been achieved since that time.

5α-Reductase is a microsomal enzyme that catalyzes the conversion of testosterone to DHT. The condition is transmitted in an autosomal recessive pattern, and only homozygous males are affected. Two 5α-reductase genes have been cloned; they encode different isoenzymes. The type 1 isoenzyme, encoded on chromosome 5, is expressed in low levels in the prostate and external genitalia. The type 2 isoenzyme is encoded on chromosome 2 and is expressed in high levels in the prostate and external genitalia (Thigpen et al., 1992b). **Male undervirilization caused by 5α-reductase deficiency is secondary to mutations in the type 2 gene.** At least 68 mutations have been identified (Berra et al., 2011; Thigpen et al., 1992a; Imperato-McGinley, 2002). Identical mutations in individuals with widely different geographic and ethnic backgrounds support the concept of mutational “hot spots” on the gene.

Individuals with this disorder present as neonates with a 46,XY karyotype and a phenotype that may vary from normal female to markedly ambiguous genitalia (more common) to penoscrotal hypospadias to the rare, isolated microphallus (Maimoun, et al. 2011). Typically, the phallus is quite small, appearing as a normal or enlarged clitoris. A urogenital sinus is present, with convergence of vaginal and urethral channels, and there is labioscrotal fusion (Fig. 48.23). The vaginal pouch is short and blind ending. Testes and epididymides are located in the labia, inguinal canals, or abdomen, and the vasa terminate in the blind-ending vaginal pouch. At puberty, partial masculinization occurs with an increase in muscle mass, development of male body habitus, increase in phallic size, and onset of erections (Peterson et al., 1977). Sperm production and fertility in affected individuals have been reported (Imperato-McGinley et al., 1982; Zhu et al., 1998). Other secondary sexual characteristics, including enlargement of the prostate and hairline recession, do not develop.

Recognition of the rare 5α-reductase patient presenting as a female phenotype suggestive of CAIS has been made (Maimoun et al., 2011) (Fig. 48.24).

On endocrine evaluation, these individuals have elevated mean plasma testosterone but low DHT levels. After hCG stimulation, the testosterone-to-DHT ratio increases to greater than 20:1. At puberty, virilization is presumed to occur because the androgen receptor binds markedly higher levels of testosterone at low affinity or because of the normal increase at puberty in the activity of the 5α-reductase type 1 isoform, resulting in sufficient DHT for virilization (MacLaughlin and Donahoe, 2004). Indeed, the enzyme abnormalities in this disorder have been shown to be biochemically heterogeneous, ranging from reduced affinity of the enzyme for testosterone and reduced affinity for nicotinamide adenine dinucleotide phosphate (NADPH) to altered pH activity profiles (Kupfer et al., 1992). The diagnosis is confirmed by sequencing the entire 5α-reductase type 2 *(SRD5A2)* gene.

The phenotypic characteristics of this disorder have helped to clarify the roles of testosterone and DHT in normal development. **Although DHT appears to be critical for the development of normal external genitalia in utero, testosterone alone appears sufficient for wolffian duct development.**

Individuals in the pedigree studied by Imperato-McGinley et al. in the Dominican Republic underwent gender reversal at puberty and were known within the community as *guevedoces* (“penis at 12” or “testicles at 12”) (Imperato-McGinley et al., 1979). This strong tendency toward reversal of gender identity in 5α-reductase deficiency has been one of the most intriguing aspects of the disorder. It has lent support to the concept that testosterone exerts the primary male imprinting effect on the brain. However, the discovery that there are two isoenzymes for 5α-reductase, only type 2 being deficient in this syndrome, allows for the possibility that 5α-reductase type 1 has some impact on the brain (Thigpen et al., 1992b). As a result, with early diagnosis of 5α-reductase deficiency, a male gender assignment is generally favored, bearing in mind that the studies strongly supporting male gender identity in this disorder were performed in sociologically unique environments (Zhu et al., 1998). Cohen-Kettenis (2005) noted 56% to 63% of 5α-reductase deficiency patients to undergo gender reversal from female to male. The clinician must be open to familial cultural considerations regarding the value of male gender and the significance of penile size. In the setting of male gender assignment, cryptorchidism and hypospadias should be surgically corrected. Fertility is possible, particularly with the advent of intrauterine insemination (Katz et al., 1997). Exogenous DHT could be used at puberty in an attempt to promote phallic growth, but it would be likely to impair spermatogenesis. For some individuals with an unambiguously female phenotype or extremely small phallic size, female gender may be assigned. For these patients, gonadectomy should be performed as early as possible and certainly well before puberty to prevent virilization. Estrogen/progestin should be administered at the expected time of puberty. Vaginoplasty and clitoral reduction may be performed within the first year of life in those with a severe defect to provide for normal appearance of the external genitalia and to allay parental anxiety.

Persistent Müllerian Duct Syndrome

Persistent müllerian duct syndrome (PMDS),* or *hernia uteri inguinale, the term originally used by Nilson (1939), characteristically describes **a group of patients with a 46,XY karyotype and normal male external genitalia but internal müllerian duct structures. Typically, these phenotypic males have unilateral or bilateral undescended testes, bilateral fallopian tubes, a uterus, and an upper vagina draining into a prostatic utricle.** The condition is commonly diagnosed after müllerian tissue is encountered during inguinal herniorrhaphy or orchidopexy (Fig. 48.25).

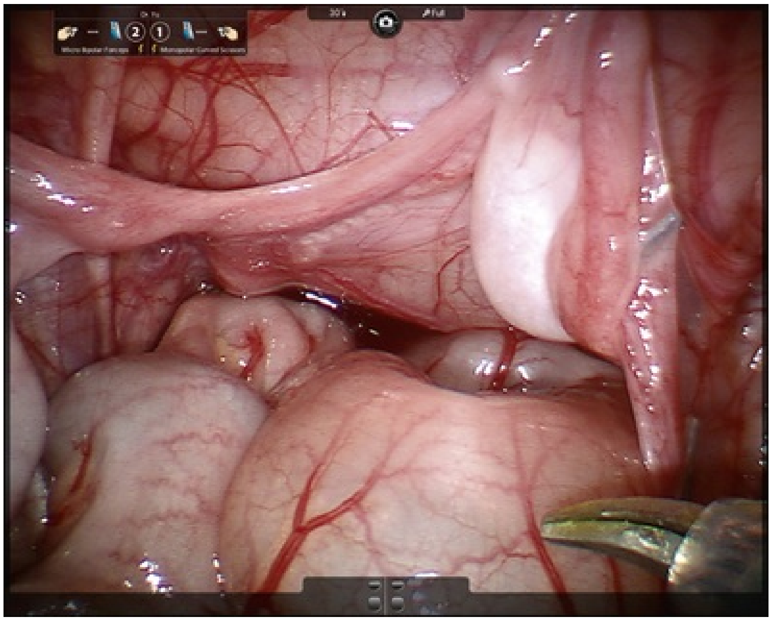

FIG. 48.25 Intraoperative view of patient with persistent müllerian duct syndrome. (Courtesy of D. Diamond, MD.)

Clarnette et al. (1997) suggested three categories for patients with PMDS: (1) the majority (60% to 70%) with bilateral intra-abdominal testes in a position analogous to ovaries; (2) a smaller group (20% to 30%) in which one testis is found in a hernia sac or scrotum in association with a contralateral inguinal hernia (the classic presentation of hernia uteri inguinale); and (3) the smallest group (10%), in which both testes are located in the same hernia sac (as a result of transverse testicular ectopia) along with the fallopian tubes and uterus (Fig. 48.26). Indeed, **PMDS is believed to be etiologically important in transverse testicular ectopia, occurring in 30% to 50% of cases** (Fujita, 1980).

The *AMH* gene was cloned in 1986 and localized on the short arm of chromosome 19 (Cates et al., 1986). It shows homology with the transforming growth factor-β superfamily of growth and differentiation factors (Imbeaud et al., 1995). **PMDS is thought to be a heterogeneous disorder genetically in which some subjects have a defect in the gene for AMH located on chromosome 19p13 and others have a defect in the gene for the AMH type II receptor located on chromosome 12q13** (MacLaughlin and Donahoe, 2004). Mutations of either the *AMH* or *AMH Receptor II* gene have been detected in 88% of cases; inheritance is autosomal recessive (Picard et al., 2017).

The treatment of persistent müllerian duct syndrome is relatively straightforward, in that all patients are phenotypic males who require orchidopexy. The cases of adult patients with associated testis tumor (most commonly seminoma) probably reflect the increased risk for malignancy in intra-abdominal undescended testes. One treatment caveat relates to management of the rudimentary müllerian structures. **The vasa deferentia are in close proximity to the uterus and proximal vagina, and historically preservation of the necessary müllerian structures to avoid injury to the vasa was recommended to preserve fertility** (Sloan and Walsh, 1976). Eleven malignancies have now been reported in retained müllerian remnants, consistent with a risk of 3% to 8%, supporting careful surgical excision, which can be performed laparoscopically (Farikullah et al., 2012).

Unclassified Forms: Mayer-Rokitansky-Küster-Hauser Syndrome

The Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome is a rare disorder entailing congenital absence of the uterus and vagina. It occurs in approximately 1 in 4000 to 5000 female births. Patients with MRKH syndrome have a 46,XX karyotype and are normal-appearing females with normal secondary sex characteristics. The external genitalia appear normal, but only a shallow vaginal pouch is present. In the typical form of the syndrome, there is symmetrical anatomy with absence of both vagina and uterus. Normal ovaries and fallopian tubes are present, and ovarian function is normal, but only symmetrical uterine remnants are found (Griffin et al., 1976). The report of a

WNT4 mutation in a woman with a phenotype resembling MRKH suggests the importance of this gene in müllerian duct formation, but the genetic basis of the disorder remains largely unknown because of lack of a sizeable family cohort (Biason-Lauber et al., 2004).

The most common clinical presentation for MRKH syndrome is primary amenorrhea, but patients may present with infertility or dyspareunia. **Upper urinary tract anomalies occur in approximately one-third of patients and include renal agenesis, pelvic kidney, and horseshoe kidney.**

Atypical forms of MRKH syndrome have been described in up to 10% of cases, in which asymmetrical uterine remnants and/or aplasia of one or both fallopian tubes is discovered. As a result, endometrial tissue or variable development of the uterus with hematometra may be present, resulting in a clinical presentation with cyclical abdominal pain. **Urinary tract anomalies occur more commonly in patients with the atypical form of MRKH.** In a study of 100 patients with MRKH syndrome, 38 of 56 patients (68%) with the atypical form of the condition had upper urinary tract abnormalities. None of the 44 patients with the typical form of MRKH syndrome had an upper urinary tract anomaly (Strubbe et al., 1994). In addition, associated cardiac anomalies have been noted in 16% of MRKH patients (Pittock et al., 2005).

A radiologic evaluation with ultrasonography and magnetic resonance imaging may define müllerian anatomy accurately in MRKH and distinguish between typical and atypical forms of the disorder (Nussbaum-Blask et al., 1991; Reinhold et al., 1997).

Treatment entails creation of a neovagina, by means of dilation or surgically, to allow for sexual function (Ismail-Pratt et al., 2007). Given the frequent success of dilation and its comparable functional outcomes to surgery, it should be the first line of therapy as recommended by the American College of Obstetrics and Gynecology (Gargollo, 2009; Morcel, 2013). If present, a hemiuterus should be removed, whereas a midline uterine structure should be hormonally suppressed rather than connecting this structure to a reconstructed vagina.

Uterine transplantation has provided a controversial fertility option for MRKH patients. The first clinical trial by Brännström included 9 women, 2 of whom required premature graft removal (Brännström, 2014). Multiple live births were reported. Overall, 17 uterine transplants have been reported worldwide by 5 groups, with 8 grafts requiring premature removal (Flyckt et al., 2018).

Future Directions

Collaborative Networking

Conducting substantive research on DSD patients presents a challenge to most individual institutions given the relative rarity of this diagnosis at any one location. Therefore, several collaborative networks have been established over the last decade to not only consolidate efforts to address research questions but also to standardize terminology, phenotype characterization, and delivery of care. The first research collaborative was the Euro-DSD, now called the international DSD (I-DSD) registry formed in 2008. This is a Web-based registry to collate cross-sectional data (genetic, biochemical, and phenotypic) and involves 33 sites across 4 continents (Sandberg et al, 2015). In the United States, the DSD-Translational Research Network (DSD-TRN) was created in 2012 to establish an infrastructure for collaborative, interdisciplinary clinical practice and research. Currently, the network includes 10 sites linked to a central registry. The overarching goal of the DSD-TRN is to standardize diagnostic and treatment protocols, including genetic evaluation, psychosocial screening, and approaches for patient and family support (Delot et al., 2017). Guidelines for genetic evaluation are especially important given the rapid development of precision medicine and the availability of advanced genomic technologies, such as next-generation DNA sequencing.

Impact of DSD Diagnosis on Caregivers

Caregivers faced with a DSD diagnosis may experience feelings of stigma, isolation, anxiety, stress, or depression. In a recent multi-institutional study, approximately 18% of parents reported experiencing significant levels of depressive symptoms and 25% reported anxiety-related symptoms (Suorsa et al., 2015). Families should routinely be offered psychological support. Future research should take into account both societal and familial influences that may alter patient and parental perceived outcomes and explore targeted interventions to improve parental competence and experienced efficacy (Wisniewski and Sandberg, 2015). Preliminary results from a recent multi-institutional study demonstrated that both parents and surgeons report similar levels of overall satisfaction with cosmetic outcomes in children with moderate-to-severe genital atypia (Bernabé et al., 2018). In the same cohort of patients 6 months after genitoplasty, the majority of parents reported minimal levels of psychological distress (Wolfe-Christensen et al., 2017). Nevertheless, approximately 25% of parents had a range of psychological symptoms that persisted from diagnosis to after genitoplasty (Wolfe-Christensen et al., 2017). Negative patient and parental experiences with the health care system have led to the formation of advocacy groups, which have been both collaborative and confrontational. Joint collaborative efforts between the medical community and advocacy groups have led to the publication of two important handbooks: *Clinical Guidelines for Management of Disorders of Sex Development in Childhood* (Accord Alliance, 2006a) and *A Handbook for Parents* (Accord Alliance, 2006b). Continued collaborative research should incorporate patient and family perspectives to assess long-term outcomes in a systematic multidisciplinary and quantitative manner.

Ethical Considerations

In contemplating surgical reconstruction for children with DSDs and ambiguous genitalia, a central ethical dilemma is the potential conflict between respect for the fundamental right of the child for physical and emotional integrity and self-determination and the right of parents to serve as surrogate decision-makers and act in their child's best interest. Often management decisions must be made based on incomplete information before it is possible to ascertain the child's self-identified gender.

The literature suggests that adult DSD patients who underwent reconstructive surgery to address genital ambiguity in childhood generally favor early surgery rather than waiting until the age of legal consent (Meyer-Bahlburg et al., 2004). However, the uncertainty of future gender identity in the face of some diagnoses favors preservation of anatomic options, whenever possible, and an open future for the child that the adult will become (Kon, 2015).

As moral agents in the face of parental and patient suffering, urologists must do their utmost to foster the physiologic and psychological health of the child while respecting parental and family wishes and rights in pursuing what they perceive as the “best interests” of their child (Diamond, 2016).

The importance of transparency with the family and patient in management of DSDs cannot be overemphasized. Uncertainties in outcomes with different gender assignment for different disorders mandates involvement of the parents in early decision-making. In the long run, transparency is essential for a healthy physician-patient relationship as the child develops into adolescence and adulthood, affording them knowledgeable engagement in DSD management for the long term.

Ultimately, management of patients with DSDs remains a challenging and humbling process. On the one hand, physicians have at their disposal sophisticated molecular biological techniques that have enabled them to identify genetic disorders responsible for the majority of DSDs. On the other hand, the mysteries of the neurophysiology of gender in the setting of sexual ambiguity remain to be solved to optimize the long-term psychosocial outcome of gender assignment for the individual patient.
